# Abstract <br> Integer programming models and exact methods for the two-dimensional two-staged knapsack problem 

Suho Kang<br>Department of Industrial Engineering<br>The Graduate School<br>Seoul National University

In this thesis, we study integer programming models and exact algorithms for the two-dimensional two-staged knapsack problems, which maximizes the profit by cutting a single rectangular plate into smaller rectangular items by two-staged guillotine cuts. We first introduce various integer programming models, including the strippacking model, the staged-pattern model, the level-packing model, and the arc-flow model for the problem. Then, a hierarchy of the strength of the upper bounds provided by the LP-relaxations of the models is established based on theoretical analysis. We also show that there exists a polynomial-size model that has not been proven yet as far as we know. Exact methods, including branch-and-price algorithms using the strip-packing model and the staged-pattern model, are also devised. Computational experiments on benchmark instances are conducted to examine the strength of upper bounds obtained by the LP-relaxations of the models and evaluate the performance of exact methods. The results show that the staged-pattern model gives a
competitive theoretical and computational performance.

## Chapter 1

## Introduction

The two-dimensional two-staged knapsack problem (2TDK) [18], which is also known as the two-dimensional two-staged cutting problem [2], maximizes a profit by cutting smaller rectangular items on a single rectangular plate without conflicts. It is a variant of the two-dimensional knapsack problem [5] with additional constraints for cutting. Conventionally, a two-dimensional knapsack problem assumes that the items have to be cut in the orthogonal style: if an item is cut from the large plate, the vertical side and the horizontal side of the item must be parallel to the vertical side and the horizontal side of the large plate, respectively. There is an additional constraint related to the guillotine cut: the plate must divide into two rectangles when being cut. Furthermore, two-staged guillotine cuts refer to the constraint that the first-stage cuts and the second-stage cuts are orthogonal. For example, in this thesis, vertical cuts can be made after all horizontal cuts are carried out.

We refer to the separate plates produced after the first-stage cuts as strips or levels. Among items in each strip, there is always the highest one. This item, which we refer to as a strip-defining item in the thesis, determines the height of the strip. There is no need for strips to be higher than their strip-defining items. Therefore, we assume that the height of the strip-defining item of each strip determines the height
of the strip. Once a strip is fixed, one should cut it vertically to produce items. We consider the inexact case, i.e., allowing trimming after the second-stage of guillotine cuts. These assumptions are practically meaningful in various industries that use sheets of material such as glass, paper, wood, and metal [10].

A simple example of two-staged guillotine cutting is represented in Figure 1.1. Both parts of Figure 1.1 are feasible two-dimensional orthogonal cuttings. On the other hand, only the right part of Figure 1.1 is a feasible two-staged two-dimensional guillotine cutting. The first-stage cuts, the second-stage cuts, and trimming are illustrated as red, blue, and green dashed lines, respectively.

(a) An infeasible case.

(b) A feasible case.

Figure 1.1: An example of two-staged two-dimensional guillotine cutting.

### 1.1 Problem Description

Formally, the problem is defined as the following. Consider a large rectangular plate $S$ with height $H$ and width $W$. There are $n$ different types of small rectangular items. For any natural number $m$, let $I_{m}=\{1, \ldots, m\}$. Then, for each $i \in I_{n}=\{1, \ldots, n\}$, an item of type $i$ has height $h_{i}$ which is less than $H$, a width $w_{i}$ which is less than $W$, a profit $p_{i}$, and an upper bound (i.e., demand) $d_{i}$ which denotes the maximum number of usage of item type $i$. We assume that all the values are integers.

If some $d_{i}$ are lower than $\left\lfloor\frac{H}{h_{i}}\right\rfloor\left\lfloor\frac{W}{w_{i}}\right\rfloor$, we call the problem is constrained. If all components of $d$ are not smaller than $\left\lfloor\frac{H}{h_{i}}\right\rfloor\left\lfloor\frac{W}{w_{i}}\right\rfloor$, we call the problem is unconstrained [13]. Also, one should separate smaller rectangles from a larger one by two-stage guillotine cuts. Our objective is to maximize the profit that can be obtained from $S$. For simplicity, we assume that the first-stage cut is performed horizontally, and the second-stage cut is performed vertically. Furthermore, we do not allow rotations of smaller rectangles and assume that $H \geq h_{1} \geq h_{2} \geq \ldots \geq h_{n}$. We denote an instance of the 2TDK by a tuple $(n, H, W, h, w, d, p)$ in this thesis.

If the problem is unconstrained, each strip used in the optimal solution has the highest profit among strips with the same height. Therefore, it can be reduced to a two-stage knapsack problem: determine the most valuable strips defined by each item, and then pack them along the vertical side within the overall height of $H$.

In the case of the constrained 2 TDK , there exists a simple reduction from the 3-PARTITION problem to the problem. The 3-PARTITION problem, which is wellknown to be NP-hard in the strong sense [11], consists of a positive integer $m$, a set $S=I_{3 m}$, a bound $B \in \mathbf{Z}_{+}$, and a value $k_{i} \in \mathbf{Z}_{+}$for each $i \in S$ such that $B / 4<k_{i}<B / 2$ and $\sum_{i \in S} k_{i}=m B$. The problem is to determine whether there exists a partition of $S$ composed of $m$ disjoint sets $S_{1}, \ldots, S_{m}$ such that for $1 \leq j \leq m$, $\sum_{i \in S_{j}} k_{i}=B$ and $\left|S_{j}\right|=3$.
Proposition 1.1. The constrained 2TDK is NP-hard in the strong sense.

Proof. For a given instance of the 3-PARTITION problem, there exists a partition of $S$ whose each subset has three components and their sum is $B$, if and only if the 2TDK instance $(3 m, m, B, h, w, d, p)$ with $\left(w_{i}, h_{i}, p_{i}, d_{i}\right)=\left(k_{i}, 1,1,1\right)$ for all $i \in I_{3 m}$ has an optimal value of 3 m .

### 1.2 Literature Review

The 2TDK has been researched since Gilmore and Gomory [12] suggested the patternbased formulations for two-dimensional cutting stock problems (2D2SP) [25]. To be more specific, the 2TDK emerges as the slave (pricing) problem of the 2D2SP, implying that they share a similar structure [10]. In this respect, solving the 2TDK is a relevant issue of solving the 2D2SP, while extending the state-of-the-art from the 2D2SP to the 2TDK has been scarce. With this necessity, we start this section by reviewing studies on the 2D2SP.

After the seminar work of Gilmore and Gomory [12], a few research suggested various integer linear programming models for the 2D2SP. Macedo et al. [20], for example, introduced the so-called arc-flow formulation, which is originated from the one-dimensional cutting stock problem. The arc-flow model requires some graphs along the vertical or horizontal side of the large plate and represents the usage of items as a feasible flow. Mrad et al. [22] proposed the pattern-based formulation for the 2D2SP, which includes both width patterns and height patterns. Silva et al. [23] suggests the one-cut model, and the close relationship between the one-cut model and the arc-flow model is well described in [21. Lastly, for a contemporary review of mathematical models for the 2D2SP, we refer readers to Kwon et al. [17], which also settled the theoretical hierarchy between the LP-relaxation values of previous models.

However, unlike the 2D2SP, few models have been proposed for the 2TDK. Gilmore and Gomory [12] developed a strip packing formulation, while two integer linear programming models based on a concept of level packing are devised by Lodi and Monaci [18]. Lodi and Monaci [18] solved their models by adding valid
inequalities to break symmetry and compared their LP-relaxation values with the strip packing model computationally, which was solved by the column generation technique. Yet, the analysis of its computational results was insufficient, and the theoretical relationship between a strip packing formulation and a level packing model has been hardly addressed.

Several exact methods have been proposed to solve problems to optimality. Hifi [13] categorized two-dimensional knapsack problems and solved the unconstrained 2TDK by dynamic programming. Belov and Scheithauer [2] implemented a branch-and-cut-and-price algorithm using Chvatal-Gomory and Gomory mixed-integer cuts, based on the strip packing formulation. The work of Belov and Scheithauer [2] seems effective in the sense that its algorithm could guarantee optimality within considerable time, but it failed to solve all instances proposed by Hifi and Roucaircol [15] to optimality. In addition, even though previous research tested their models computationally, more elaborate experiments are required for investigating the pros and cons of each method.

In the aspect of heuristic algorithms for the 2TDK, Hifi and M'Hallah [14] suggested strip generation algorithms based on the greedy algorithm and the hillclimbing algorithm. Conducting computational experiments to evaluate the effectiveness of their models, it verified that its algorithm could find near-optimal solutions in a relatively short time. Alvarez-Valdes et al. (1) developed heuristic algorithms with bottom-left procedures and path relinking methods. It was a time-efficient algorithm, even finding a better solution to the instance that the branch-and-cut-and-price algorithm failed to find the optimal solution within a relatively longer time [2]. However, no theoretical guarantees have been made for the effectiveness of
heuristics.
Despite sharing the two-staged guillotine cutting constraint, extending models from the 2D2SP to the 2TDK have not been proposed much yet. Even for the existing models and methods, their strengths and weakness have not been fully investigated both computationally and theoretically. We, therefore, have tried to overcome the limitation and fill the unanswered gap from previous studies.

### 1.3 Contributions

In this study, questions which have been discussed insufficiently from the perspective of the 2TDK are analyzed thoroughly. Our contributions can be summarized as follows:
(a) We extend some existing models for the 2D2SP to the 2 TDK and add a set of valid inequalities to the level-packing model proposed by Lodi and Monaci [18]. The added inequalities enhance the LP-relaxation value and ease analyzing the relationship between other models.
(b) In addition, the LP-relaxation values of models are analyzed theoretically. We derive that the LP-relaxation values of some models satisfy a specific inequality and prove that there is a tight example.
(c) Furthermore, we propose a novel polynomial-size formulation for the first time, using a result provided by Eisenbrand and Shmonin [8].
(d) Finally, we propose exact algorithms for the 2TDK. We construct branch-andprice algorithms for the pattern-based models and present a branch-and-cut algorithm for the modified level-packing model. Various computation experiments are conducted to analyze the characteristics of each model in their real usage.

### 1.4 Organization of the Thesis

This thesis is organized as follows. In Chapter 2, we shortly derive the complexity of solving the 2TDK and introduce various integer linear programming models for the 2TDK. The relationship between the LP-relaxation values among them is discussed in Chapter 3. We also suggest a polynomial-size model for the 2TDK for the first time. Then, We propose exact algorithms for some models in Chapter 4. In Chapter 5, we compare the LP-relaxation values computationally and analyze their performance of solving problems to optimality. This thesis ends up with the main conclusion in Chapter 6.

## Chapter 2

## Integer Programming Models for the 2TDK

### 2.1 Pattern-based Model

We start this section by introducing the staged-pattern model from Mrad et al. [22] and Kwon et al. [17. The main idea of this formulation is to utilize the concept of a width pattern and a height pattern. We represent a width pattern $q$ as an $n$ dimensional nonnegative integer vector $a_{q}=\left(a_{q 1}, \ldots, a_{q n}\right)$, where $a_{q i}$ is the number of pieces of $i$ th item type for each $i \in I_{n}$ in a width pattern $q$. For a given $n$ dimensional vector $u$, we define $P_{W}(u)$ as a set of width patterns $q$ satisfying the following:

$$
P_{W}(u)=\left\{q \mid \sum_{i \in I_{n}} w_{i} a_{q i} \leq W, a_{q} \leq u\right\}
$$

Likewise, we represent a height pattern $r$ as an $n$-dimensional nonnegative integer vector $b_{r}=\left(b_{r 1}, \ldots, b_{r n}\right)$ where $b_{r i}$ is the number of pieces of $i$ th item type used for each $i \in I_{n}$ in a height pattern $r$. For a given $n$-dimensional vector $v$, we define $P_{H}(v)$ as a set of height patterns $r$ satisfying the following:

$$
P_{H}(v)=\left\{r \mid \sum_{i \in I_{n}} h_{i} b_{r i} \leq H, b_{r} \leq v\right\} .
$$

As a special case, we define $P_{W}(\infty)$ and $P_{H}(\infty)$ as the following:

$$
P_{W}(\infty)=\left\{q \mid \sum_{i \in I_{n}} w_{i} a_{q i} \leq W\right\}
$$

and

$$
P_{H}(\infty)=\left\{r \mid \sum_{i \in I_{n}} h_{i} b_{r i} \leq H\right\} .
$$

Note that $P_{W}(\infty)$ and $P_{H}(\infty)$ corresponds to the unconstrained case. In addition, for a given $n$-dimensional vector $u$ and a width pattern $q \in P_{W}(u)$, let $t(q)$ denote the minimum index which is in a support of $a_{q}$. For a strip corresponding to the width pattern $q$, the strip-defining item is an item of type $t(q)$. Also, the height of the strip corresponds to $h_{t(q)}$.

In the example of Figure 2.1 and Figure 2.2, the left part of Figure 2.1 shows that two first-stage cuts divide the large plate into three strips. The right part of Figure 2.1 illustrates second-stage cuts and trimming to each strip. Then, the firststage cuts are equivalent to a single height pattern, and second-stage cuts including trimming are equivalent to a single width pattern. The result of cuts is the same as Figure 2.2 .

Figure 2.1: An illustration of two-stage guillotine cutting.

Figure 2.2: An illustration of the large plate.

Utilizing these concepts, we represent the staged-pattern model for the 2TDK as follows:

$$
\begin{align*}
\operatorname{SM}(u, v): \text { maximize } & \sum_{q \in P_{W}(u)} \sum_{i \in I_{n}} p_{i} a_{q i} x_{q} \\
\text { subject to } \quad & \sum_{q \in P_{W}(u)} a_{q i} x_{q} \leq d_{i}, \quad \forall i \in I_{n},  \tag{2.1}\\
& \sum_{r \in P_{H}(v)} b_{r i} y_{r} \geq \sum_{q \in P_{W}(u), t(q)=i} x_{q}, \quad \forall i \in I_{n},  \tag{2.2}\\
& \sum_{r \in P_{H}(v)} y_{r} \leq 1,  \tag{2.3}\\
& x_{q} \in \mathbf{Z}_{+}, \quad \forall q \in P_{W}(u), \\
& y_{r} \in \mathbf{Z}_{+}, \quad \forall r \in P_{H}(v) . \tag{2.4}
\end{align*}
$$

A decision variable $x_{q}$ denotes how much width pattern $q$ has been used, and a decision variable $y_{r}$ represents the amount of height pattern $r$ having been used. Constraints 2.1 limit the maximum usage of each item type to its demand, and a constraint 2.2 indicates that usage of a width pattern is only available when a chosen height pattern allows the usage of the corresponding strip-defining item.

On the other hand, the strip packing model originated from Gilmore and Gomory [12] only exploits the concept of the width pattern. We propose the mathematical
formulation of the strip packing model as follows:

$$
\begin{align*}
\operatorname{PM}(u): \quad \text { maximize } & \sum_{q \in P_{W}(u)} \sum_{i \in I_{n}} p_{i} a_{q i} x_{q} \\
\text { subject to } & \sum_{q \in P_{W}(u)} a_{q i} x_{q} \leq d_{i}, \quad \forall i \in I_{n},  \tag{2.5}\\
& \sum_{q \in P_{W}(u)} h_{t(q)} x_{q} \leq H,  \tag{2.6}\\
& x_{q} \in \mathbf{Z}_{+}, \quad \forall q \in P_{W}(u) .
\end{align*}
$$

A decision variable $x_{q}$ has the same meaning as $x_{q}$ in $\operatorname{SM}(u, v)$. Constraints 2.5 describe the demand constraint, and a constraint (2.6) indicates that the total height cannot exceed $H$. Note that $\operatorname{PM}(u)$ becomes a valid formulation for the 2TDK when $u \geq d$. Similarly, $\operatorname{SM}(u, v)$ becomes a valid formulation when $u \geq d$ and $v \geq d$. Besides, because the number of components is exponentially many in a pattern set $P_{W}(u)$ (resp. $\left.P_{H}(v)\right)$ as $u \geq d$ (resp. $v \geq d$ ), $\mathrm{PM}(u)$ and $\mathrm{SM}(u, v)$ are not polynomialsize formulations.

Then, for a given 2TDK instance $(n, H, W, h, w, d, p)$, let $z^{*}$ be the optimal objective value of any valid formulation for the 2 TDK and $z_{\mathrm{LP}}^{\text {model }}$ be the optimal objective value of the LP-relaxation of the corresponding model of the 2TDK. For example, $z_{\mathrm{LP}}^{\mathrm{PM}(u)}$ is the optimal objective value of the LP-relaxation value of $\operatorname{PM}(u)$. With these symbols, the following proposition hold:

Proposition 2.1. $z^{*} \leq z_{L P}^{S M(d, d)} \leq z_{L P}^{P M(d)}$ and $z_{L P}^{S M(d, d)} \leq z_{L P}^{S M(\infty, \infty)}$.

Proof. For any feasible solution $(x, y)$ in the LP-relaxation of $\operatorname{SM}(u, v), x$ is a feasible solution in the LP-relaxation of $\mathrm{PM}(u)$. Also, since $P_{W}(d) \subset P_{W}(\infty)$ and $P_{H}(d) \subset$
$P_{H}(\infty), z_{\mathrm{LP}}^{\mathrm{SM}(d, d)} \leq z_{\mathrm{LP}}^{\mathrm{SM}(\infty, \infty)}$ holds.
Interestingly, $z_{\mathrm{LP}}^{\mathrm{SM}(\infty, \infty)}$ is not always less than $z_{\mathrm{LP}}^{\mathrm{PM}(d)}$. We verify this through some benchmark instances in Chapter 5, which refute $z_{\mathrm{LP}}^{\mathrm{SM}(\infty, \infty)} \leq z_{\mathrm{LP}}^{\mathrm{PM}(d)}$.

Proposition 2.2. $S M(d, d)$ is still a valid formulation when constraints (2.4) are relaxed.

Proof. Let a feasible solution $\left(x^{*}, y^{*}\right)$ of $\operatorname{SM}(d, d)$ with constraints (2.4) relaxed. We will prove that $x^{*}$ is a feasible solution of $\operatorname{PM}(d)$. Note that the following holds:

$$
\sum_{q \in P_{W}(d)} h_{t(q)} x_{q}^{*}=\sum_{i i n I_{n}} h_{i}\left(\sum_{q \in P_{W}(d), t(q)=i} x_{q}^{*}\right) \leq \sum_{i \in I_{n}} \sum_{r \in P_{H}(d)} h_{i} b_{r i} y_{r}^{*}
$$

Since $\sum_{i \in I_{n}} h_{i} b_{r i} \leq H$ for all $r \in P_{H}(d)$ and $\sum_{r \in P_{H}(d)} y_{r}^{*} \leq 1$, the next inequality satisfies:

$$
\sum_{i \in I_{n}} \sum_{r \in P_{H}(d)} h_{i} b_{r i} y_{r}^{*} \leq \sum_{r \in P_{H}(d)} y_{r}^{*}\left(\sum_{i \in I_{n}} h_{i} b_{r i}\right) \leq \sum_{r \in P_{H}(d)} H y_{r}^{*} \leq H .
$$

Therefore, $x^{*}$ satisfies all constraints in $\operatorname{PM}(d)$.
Then, for any feasible solution $x^{*}$ in $\operatorname{PM}(d),\left(b_{1}^{*}, \ldots, b_{n}^{*}\right)$ defined as follows is in $P_{H}(d):$

$$
b_{i}=\sum_{q \in P_{W}(u), t(q)=i} x_{q}^{*}, \quad \forall i \in I_{n} .
$$

Let $b_{r^{*}}=\left(b_{1}^{*}, \ldots, b_{n}^{*}\right)$. Then, let $y_{r^{*}}=1$ and $y_{r}=0$ for other $r \in P_{H}(d)$. It is clear that $\left(x^{*}, y\right)$ is a feasible solution of $\operatorname{SM}(d, d)$ with constraints (2.4) relaxed.

In the aspect of simplicity, when it comes to height patterns, we can corpo-
rate item types with the same height into a single item type. To elaborate, let $\left\{h_{(1)}, \ldots, h_{(m)}\right\}$ be the minimal representation of a height set $\left\{h_{1}, \ldots, h_{n}\right\}$. Then, redefine a height pattern $\gamma$ as a height pattern vector $\left(b_{\gamma 1}, \ldots, b_{\gamma m}\right) \in \mathbf{Z}_{+}^{m}$ satisfying $\sum_{i \in I_{m}} h_{(i)} b_{\gamma i} \leq H$ and $b_{\gamma i} \leq \sum_{j \in I_{n}, h_{j}=h_{(i)}} d_{j}$ for $i \in I_{m}$. Let the height pattern set be $P_{H}^{2}(d)$. Then, the similar staged-pattern model SM-HA is represented as following:

$$
\begin{align*}
& \text { SM-HA : } \quad \text { maximize } \sum_{q \in P_{W}(d)} \sum_{i \in I_{n}} p_{i} a_{q i} x_{q} \\
& \text { subject to } \quad \sum_{q \in P_{W}(d)} a_{q i} x_{q} \leq d_{i}, \quad \forall i \in I_{n},  \tag{2.7}\\
& \sum_{r \in P_{H}^{2}(d)} b_{r i} y_{r} \geq \sum_{q \in P_{W}(u), h_{t(q)}=h_{(i)}} x_{q}, \quad \forall i \in I_{m},  \tag{2.8}\\
& \sum_{r \in P_{H}^{2}(d)} y_{r} \leq 1,  \tag{2.9}\\
& x_{q} \in \mathbf{Z}_{+}, \quad \forall q \in P_{W}(d), \\
& y_{r} \in \mathbf{Z}_{+}, \quad \forall r \in P_{H}^{2}(d) .
\end{align*}
$$

Note that SM-HA is a valid formulation, and the following proposition holds:
Proposition 2.3. $z_{L P}^{S M(d, d)} \leq z_{L P}^{S M-H A} \leq z_{L P}^{P M(d)}$.

Proof. Any feasible solution of the LP-relaxation of $\operatorname{SM}(d, d)$ is a feasible solution to the LP-relaxation of SM-HA. Also, a constraint (2.9) forces $x$ in the LP-relaxation of SM-HA to satisfy the constraint 2.6 . Therefore, $z_{\mathrm{LP}}^{\mathrm{SM}-\mathrm{HA}} \leq z_{\mathrm{LP}}^{\mathrm{PM}(d)}$ holds.

### 2.2 Arc-flow Model

With some modifications of the network model suggested by Macedo et al. [20], similar networks can be designed for the 2TDK. For each instance of the 2TDK, the arc-flow model generates $n+1$ directed acyclic graphs: $G^{0}=\left(V^{0}, A^{0}\right), G^{1}=\left(V^{1}, A^{1}\right)$, $\ldots, G^{n}=\left(V^{n}, A^{n}\right)$. A graph $G^{0}$ represents how much each item has been used as a strip-defining item, and the other graphs represent strips that are characterized by the item type of corresponding indices. Graph $G^{0}$ is given by the set of nodes $V^{0}=\{0,1, \ldots, H\}$ and the set of $\operatorname{arcs} A^{0}=\{(a, b, k) \mid 0 \leq a<b \leq H, b-a=$ $\left.h_{k}, k \in I_{n}\right\} \cup N_{H}$, where $N_{H}:=\{(i, i+1,0) \mid i \in\{0, \ldots, H-1\}\}$. Note that $N_{H}$ represents empty space. Likewise, for $j \in I_{n}$, graph $G^{j}$ is given by the set of nodes $V^{j}=\{0, \ldots, W\}$ and the set of $\operatorname{arcs} A^{j}=\left\{(a, b, i) \mid 0 \leq a<b \leq W, b-a=w_{i}, i \in\right.$ $\{j, \ldots, n\}\} \cup N_{W}^{j}$, where $N_{W}^{j}:=\{(i, i+1,0) \mid i \in\{0, \ldots, W-1\}\}$. A profit of each $\operatorname{arc}(a, b, i)$ in $G^{j}$, which we denote by $\pi_{(a, b, i)}^{j}$, is $p_{i}$ for $i \in I_{n}$. For the other arcs, they have zero profits. Decision variables are the amount of flows in each arc, and the overall mathematical representation of an arc-flow model for the 2TDK is as follows:

AF : maximize $\sum_{j \in I_{n}} \sum_{(a, b, i) \in A^{j}} \pi_{(a, b, i)}^{j} x_{(a, b, i)}^{j}$
subject to $\sum_{(a, b, i) \in A^{0}} x_{(a, b, i)}^{0}-\sum_{(b, c, k) \in A^{0}} x_{(b, c, k)}^{0}= \begin{cases}-1 & \text { if } b=0 \\ 0 & \text { if } b=1, \ldots, H-1, \\ 1 & \text { if } b=H\end{cases}$

$$
\begin{equation*}
\sum_{\left(c, c+h_{j}, k\right) \in A^{0}} x_{\left(c, c+h_{j}, k\right)}^{0}-z^{j}=0, \quad \forall j \in I_{n}, \tag{2.11}
\end{equation*}
$$

$$
\sum_{(d, e, i) \in A^{j}} x_{(d, e, i)}^{j}-\sum_{(e, f, k) \in A^{j}} x_{(e, f, k)}^{j}
$$

$$
= \begin{cases}-z^{j} & \text { if } e=0  \tag{2.13}\\ 0 & \text { if } e=1, \ldots, W-1, \quad \forall j \in I_{n}, \\ z^{j} & \text { if } e=W\end{cases}
$$

$$
\begin{equation*}
\sum_{j \in I_{n}} \sum_{\left(f, f+w_{i}, i\right) \in A^{j}} x_{\left(f, f+w_{i}, i\right)}^{j} \leq d_{i}, \quad \forall i \in I_{n}, \tag{2.14}
\end{equation*}
$$

All variables are nonnegative integers.

The objective function (2.10) describes the overall profit. Constraints (2.11), (2.12), and (2.13) determine how much flow can run in each graph. Lastly, constraints (2.14) represent demand constraints. Note that the size of AF is pseudo-polynomial since it depends on numeric values of $H$ and $W$. For some arc-reduction techniques and motivations, see Martinovic et al. [21].

### 2.3 Level Packing Model

Lodi and Monaci [18] regarded items of the same type as separate item types which all have a unit demand and share the same sizes and profit. If the demand for each item is a unit amount, all strip-defining items are characterized by their types. In this view, Lodi and Monaci [18] suggested two formulations which divide $d_{i}$ items of $i$ type into $d_{i}$ different types for all $i \in\{1, \ldots, n\}$. These new $d_{i}$ types of items share the same height, width, profit, and demand value as $\left(h_{i}, w_{i}, p_{i}, 1\right)$.

Then, each 2TDK instance $\mathbf{I}=(n, H, W, h, w, d, p)$ transforms into new instance $\hat{\mathbf{I}}$ with the number of item types $N=\sum_{i=1}^{n} d_{i}$. In detail, we define $\alpha_{j}=\sum_{i=1}^{j} d_{i}$ for any $j \in I_{n}$ and $\beta_{k}=\min \left\{t: 1 \leq t \leq n, \alpha_{t} \geq k\right\}$ for any $k \in I_{N}$. Then, we express the transformed instance $\hat{\mathbf{I}}$ as the following:

$$
\hat{\mathbf{I}}=(N, H, W, \hat{h}, \hat{w}, \hat{d}, \hat{p}),
$$

where $\hat{h}_{k}=h_{\beta_{k}}, \hat{w}_{k}=w_{\beta_{k}}, \hat{d}_{k}=1$, and $\hat{p}_{k}=p_{\beta_{k}}$ for any $k \in I_{N}$. The level-packing formulation LM that was proposed in Lodi and Monaci [18] is as follows:

LM : maximize $\sum_{j=1}^{N} p_{\beta_{k}} \sum_{k=1}^{j} x_{j k}$

$$
\begin{array}{ll}
\text { subject to } & \sum_{k=1}^{j} x_{j k} \leq 1, \quad \forall j \in\{1, \ldots, N\} \\
& \sum_{j=k+1}^{N} w_{\beta_{j}} x_{j k} \leq\left(W-w_{\beta_{k}}\right) x_{k k}, \quad \forall k \in\{1, \ldots, N\} \\
& \sum_{k=1}^{N} h_{\beta_{k}} x_{k k} \leq H  \tag{2.18}\\
& x_{j k} \in\{0,1\}, \quad \forall k \in\{1, \ldots, N\}, \quad \forall j \in\{k, \ldots, N\}
\end{array}
$$

In this formulation, a decision variable $x_{j k}$ represents the usage of $j$ th item in a strip that is defined by stip-defining item of $k$ th original type.

Against previous research including Belov and Scheithauer [2], we claim that the above model LM is a pseudo-polynomial-size model since the number of variables depends on a numeric value of the sum of demands, not the input size of it. We also add a set of constraints 2.21 that restricts the formulation to properly allocate items in any fractional used strip. These inequalities not only improve the quality of the LP-relaxation value but also ease comparing the structure of the formulation to other models. This modified model is named as ML, stands for modified level packing. The mathematical formulation of ML is as follows:

ML: maximize 2.15
subject to (2.15), 2.16, 2.17), 2.18, and 2.19

$$
\begin{equation*}
x_{j k} \leq x_{k k}, \quad \forall k \in\{1, \ldots, N\}, \quad \forall j \in\{k+1, \ldots, N\} . \tag{2.20}
\end{equation*}
$$

Note that each of the constraints 2.21 is a valid inequality that sets the stripdefining item to the most used item in its corresponding strip.

## Chapter 3

## Theoretical Analysis of Integer Programming Models

In Section 3.1 and 3.2, we focus on four different types of models: a strip packing model, a staged-pattern model, an arc-flow model, and a modified level packing model. We thoroughly analyze the hierarchical relationship between the LPrelaxation of each model. In Section 3.3, we propose the polynomial-size formulation for the first time.

### 3.1 Upper Bounds of AF and $\operatorname{SM}(\infty, \infty)$

We summarize the equivalence between the upper bounds provided by the LPrelaxation of AF and $\mathrm{SM}(\infty, \infty)$ as the following proposition:

Proposition 3.1. $z_{L P}^{A F}=z_{L P}^{S M(\infty, \infty)}$
Proof. As all graphs in the arc-flow model are acyclic, any feasible flow in $G_{0}, \ldots, G_{n}$ is decomposed into the simple paths from the start node to the end node. Since a possible simple path in $G_{0}$ is corresponding to a height-pattern in $P_{H}(\infty)$ and a possible simple path in $G_{1}, \ldots, G_{n}$ is corresponding to a width-pattern in $P_{W}(\infty)$. In addition, each pattern corresponds to some simple paths of a corresponding graph. Therefore, solutions to the LP-relaxations of AF and $\mathrm{SM}(\infty, \infty)$ are convertible.

### 3.2 Upper Bounds of $\operatorname{ML}, \operatorname{PM}(d)$, and $\operatorname{SM}(d, d)$

To directly compare instance $\mathbf{I}$ and instance $\hat{\mathbf{I}}$, define a set of width pattern vectors $Q_{W}$ and a set of height pattern vectors $Q_{H}$ as follows:

$$
Q_{W}=\left\{a_{q} \in \mathbf{Z}_{+}^{n} \mid q \in P_{W}(d)\right\}=\left\{a \in \mathbf{Z}_{+}^{n} \mid \sum_{i \in I_{n}} w_{i} a_{i} \leq W, a \leq d\right\}
$$

and

$$
Q_{H}=\left\{b_{r} \in \mathbf{Z}_{+}^{n} \mid r \in P_{H}(d)\right\}=\left\{b \in \mathbf{Z}_{+}^{n} \mid \sum_{i \in I_{n}} h_{i} b_{i} \leq H, b \leq d\right\}
$$

Also, define a set of width pattern vectors $\hat{Q}_{W}$ and a set of height pattern vectors $\hat{Q}_{H}$ in the aspect of instance $\hat{\mathbf{I}}$ :

$$
\hat{Q}_{W}=\left\{\hat{a} \in \mathbf{B}^{N} \mid \sum_{k \in I_{N}} w_{\beta_{k}} \hat{a}_{k} \leq W\right\}=\left\{\hat{a}^{1}, \ldots, \hat{a}^{M_{W}}\right\},
$$

and

$$
\hat{Q}_{H}=\left\{\hat{b} \in \mathbf{B}^{N} \mid \sum_{k \in I_{N}} h_{\beta_{k}} \hat{b}_{k} \leq H\right\}=\left\{\hat{b}^{1}, \ldots, \hat{b}^{M_{H}}\right\}
$$

where $M_{W}$ and $M_{H}$ correspond to $\left|\hat{Q}_{W}\right|$ and $\left|\hat{Q}_{H}\right|$, respectively.
Note that an element of $\hat{Q}_{W}$ is an "extended version" of an element of $Q_{W}$. To elaborate their relationship, we define an onto function $f: \hat{Q}_{W} \rightarrow Q_{W}$ as follows:

$$
f(\hat{a})_{i}=\sum_{j \in I_{N}, \beta_{j}=i} \hat{a}_{j}, \forall i \in I_{n}, \forall \hat{a} \in \hat{Q}_{W} .
$$

For any $i \in I_{M_{W}}$, there exists a width pattern $q \in P_{W}(d)$ such that $f\left(\hat{a}^{i}\right)=a_{q}$, and let $\hat{c}_{i}$ be the value of $h_{t(q)}$. Indeed, $\hat{c}_{i}$ is the height of the strip-defining item with the respect of the instance $\hat{\mathbf{I}}$. Then, the following formulation PM2 is a valid formulation for the 2TDK:

$$
\begin{aligned}
\text { PM2 : } \quad \text { maximize } & \sum_{i=1}^{M_{W}} \sum_{k=1}^{N} p_{\beta_{k}} \hat{a}_{k}^{i} x_{i} \\
\text { subject to } & \sum_{i=1}^{M_{W}} \hat{a}_{k}^{i} x_{i} \leq 1, \quad \forall k \in I_{N} \\
& \sum_{i=1}^{M_{W}} \hat{c}_{i} x_{i} \leq H \\
& x \in B^{M_{W}} .
\end{aligned}
$$

To help understand, define an instance $\mathbf{I}_{1}=(2,3,3, h, w, d, p)$ with $h=(2,1)$, $w=(2,1), d=(1,2)$, and $p=(4,1)$. Then, the corresponding $\hat{\mathbf{I}}_{1}$ is defined as $(3,3,3, \hat{h}, \hat{w}, \hat{d}, \hat{p})$ with $\hat{h}=(2,1,1), \hat{w}=(2,1,1), \hat{d}=(1,1,1)$, and $\hat{p}=(4,1,1)$. Then, $Q_{W}$ and $\hat{Q}_{W}$ are as follows:

$$
Q_{W}=\{(1,0),(1,1),(0,1),(0,2)\}
$$

and

$$
\hat{Q}_{W}=\{(1,0,0),(1,1,0),(1,0,1),(0,1,0),(0,0,1),(0,1,1)\}
$$

Note that for any $j \in I_{n}$, if $\left(\hat{a}_{1}, \ldots, \hat{a}_{\alpha_{j-1}+1}, \ldots, \hat{a}_{\alpha_{j}}, \ldots, \hat{a}_{N}\right) \in \hat{Q}_{W}$, then so does $\left(\hat{a}_{1}, \ldots, \hat{a}_{\alpha_{j-1}+1}^{*}, \ldots, \hat{a}_{\alpha_{j}}^{*}, \ldots, \hat{a}_{N}\right)$, where $\left(\hat{a}_{\alpha_{j-1}+1}^{*}, \ldots, \hat{a}_{\alpha_{j}}^{*}\right)$ is any permutation of
$\left(\hat{a}_{\alpha_{j-1}+1}, \ldots, \hat{a}_{\alpha_{j}}\right)$. We introduce some nontrivial properties related to $\operatorname{PM}(d)$.
Proposition 3.2. $z_{L P}^{P M 2}=z_{L P}^{P M(d)}$

Proof. For each $q \in P_{W}(d)$, let $P(q)=\left\{i \in I_{M_{W}} \mid f\left(\hat{a}^{i}\right)=a_{q}\right\}$. The conversion from the feasible solution $x^{\mathrm{PM}(d)}$ of the LP-relaxation of $\operatorname{PM}(d)$ to the feasible solution $x^{\mathrm{PM} 2}$ of the LP-relaxation of PM2 can be easily shown by setting $x_{j}^{\mathrm{PM} 2}=$ $x_{q}^{\mathrm{PM}(d)} /|P(q)|$, for $j \in I_{M_{W}}$ and $q \in P_{W}(d)$ satisfying $f\left(\hat{a}^{j}\right)=a_{q}$. Then, $\sum_{i=1}^{M_{W}} \hat{\alpha_{k}}{ }^{i} x_{i}^{\mathrm{PM} 2}$ $=\left(\sum_{q \in P_{W}(d)} a_{q \beta_{k}} x_{q}^{\mathrm{PM}(d)}\right) / d_{\beta_{k}} \leq 1$, for all $k \in I_{N}$. The other direction is easily shown by setting $x_{q}^{\mathrm{PM}(d)}=\sum_{i \in P(q)} x_{i}^{\mathrm{PM} 2}$.

Proposition 3.3. $z_{L P}^{P M 2} \leq z_{L P}^{M L}$.

Proof. For each $i \in I_{M_{W}}$, let $\hat{t}(i)$ denote the minimum index which is in the support of $\hat{a}^{i}$. Also, let the support of $\hat{a}^{i}$ be $\hat{S}_{i}$. Then, given the feasible solution $x^{\mathrm{PM} 2}$ of the LP-relaxation of PM2, we can construct a feasible solution $x^{\mathrm{ML}}$ to the LP-relaxation of ML defined as follows:

$$
x_{j k}^{\mathrm{ML}}=\sum_{i \in I_{M_{W}}, \hat{t}(i)=k, k \in \hat{S}_{i}} x_{i}^{\mathrm{PM} 2}, \quad \forall k \in\{1, \ldots, N\}, \quad \forall j \in\{k, \ldots, N\} .
$$

Then, for each $k \in I_{N}$, let $y_{k}=\left(x_{k k}, \ldots, x_{N k}\right)$. Define $P_{k}$ as follows:

$$
\begin{aligned}
P_{k}=\left\{y_{k} \in[0,1]^{N-k+1} \mid\right. & \sum_{j=k+1}^{N} w_{\beta_{j}} x_{j k} \leq\left(W-w_{\beta_{k}}\right) x_{k k}, \\
& x_{j k} \leq x_{k k}, \quad \forall j \in\{k+1, \ldots, N\}, \\
& \left.x_{j k} \in[0,1], \quad \forall j \in\{k, \ldots, N\}\right\} .
\end{aligned}
$$

Proposition 3.4. Extreme points in $P_{k}$, which satisfy $N-k+1$ linearly independent inequalities as equality, can be represented as the form of sy, where $s \in[0,1]$ is a scalar and elements of $y \in[0,1]^{N-k+1}$ are all binary except at most one component.

Proof. We show that if there exists $i, j$ such that $i \neq j, x_{i k} \neq x_{k k}, x_{i k} \neq 0, x_{j k} \neq x_{k k}$, and $x_{j k} \neq 0$, then corresponding $y_{k}$ cannot be an extreme point in $P_{k}$. Due to the assumption, none of $x_{i k}=x_{k k}, x_{j k}=x_{k k}, x_{i k}=0, x_{j k}=0, x_{i k}=1$, or $x_{j k}=1$ is satisfied. Therefore, even though $\sum_{j=k+1}^{N} w_{\beta_{j}} x_{j k}=\left(W-w_{\beta_{k}}\right) x_{k k}$ satisfies, at most $N-k$ linearly independent constraints can be satisfied in equality.

Proposition 3.5. $z_{L P}^{M L} \leq 2 z_{L P}^{P M 2}$.

Proof. To prove the proposition, it is sufficient to describe the procedure to construct a feasible solution of the LP-relaxation of PM2 from a feasible solution of the LPrelaxation of ML with at least half of its original value. Since any point in a polytope is a linear combination of its extreme points, we focus on converting extreme points of $P_{k}$ into width patterns.

By Proposition 3.4, extreme points in $P_{k}$ can be represented as the form of $s y$, where $s \in[0,1]$ is a scalar and elements of $y \in[0,1]^{N-k+1}$ are all binary except at most one component. Also, there always exist $s$ and $y$ such that the first element of $y$ is unit amount. If there is a fractional element in $y$, setting it to zero and adding $k-1$ zeros at the foremost of $y$ transforms $y$ into a feasible width pattern vector of the instance $\hat{\mathbf{I}}$ (i.e., an element of $\hat{Q}_{W}$ ). Note that $P_{k}$ corresponds to the constraints (2.17), (2.21), and (2.19) for fixed $k \in I_{N}$.

For any $s y^{c} \in P_{k}$ whose components of $y^{c}$ are all binary except at most one component, let the corresponding width pattern vector of $y^{c}$ by dropping the frac-
tional component and adding $k-1$ zeros at the foremost be $\hat{a}^{c} \in \hat{Q}_{W}$. If there is no fractional component in $y^{c}$, then adding $k-1$ zeros in the foremost of $y^{c}$ makes the vector exactly same as $\hat{a}^{c}$. If there is a fractional component in $y^{c}$, let the fractional index(starts from $k$ ) be $e$ and its value be $y_{e}^{c}$. If $\sum_{l=k, l \neq e}^{N} p_{\beta_{l}} y_{l}^{c} \leq p_{\beta_{e}} y_{e}^{c}$, then one may use width-pattern of only using the item $e$ (corresponding to the $e$ th unit vector in $\mathbf{R}^{N}$ ) instead of $y^{c}$ if one can double the profit, because $\sum_{l=k, l \neq e}^{N} p_{\beta_{l}} y_{l}^{c}+p_{\beta_{e}} y_{e}^{c} \leq$ $2 p_{\beta_{e}} y_{e}^{c} \leq 2 p_{\beta_{e}}$, and $h_{e} \leq h_{k}$. Otherwise, one may use width-pattern vector $\hat{a}^{c}$ if one can double the profit, because $\sum_{l=k, l \neq e}^{N} p_{\beta_{l}} y_{l}^{c}+p_{\beta_{e}} y_{e}^{c} \leq 2 \sum_{l=k, l \neq e}^{N} p_{\beta_{l}} y_{l}^{c}$. Therefore, the above procedure constructs a desirable feasible solution in PM2.

Applying similar analysis to PM2, define $\hat{Q}_{H}^{W}$ as following:

$$
\hat{Q}_{H}^{W}=\left\{y \in[0,1]^{M_{W}} \mid \sum_{i=1}^{M_{W}} \hat{c}_{i} y_{i} \leq H\right\}
$$

Note that unlike $\hat{Q}_{H}$, each element in $\hat{Q}_{H}^{W}$ describes the amounts of width patterns with total height equal or less than $H$. Also, an extreme point of $\hat{Q}_{H}^{W}$ has at most one fractional support. Let $R=\left\{\hat{r}^{1}, \ldots, \hat{r}^{M_{R}}\right\}$ denote the set of extreme points of $\hat{Q}_{H}^{W}$. For each $j \in I_{M_{R}}, \hat{r}^{j}$ is an $M_{W}$-dimensional vector. Let $V \in \mathbf{R}^{M_{W} \times M_{R}}$ be a matrix which each of its column is corresponding to the element of $R$ and $U \in \mathbf{B}^{N \times M_{W}}$ be a matrix which each of its column is corresponding to the vector in $\hat{P}_{W}$. The LP-relaxation of PM2 is equivalent to the following model PM3:

PM3: maximize $\hat{p}^{T} U V x$

$$
\text { subject to } U V x \leq \hat{d},
$$

$$
\begin{aligned}
& \sum_{j \in I_{M_{R}}} x_{j} \leq 1, \\
& x_{j} \geq 0, \quad \forall j \in I_{M_{R}}
\end{aligned}
$$

Then, let SM2 be the formulation of PM3 with rounding down the components in V. Note that for any $j \in I_{M_{R}},\left\lfloor\hat{r}^{j}\right\rfloor$ is a "extended version" of the height pattern.

$$
\begin{array}{ll}
\text { SM2 : } \quad \text { maximize } \quad \hat{p}^{T} U\lfloor V\rfloor x \\
\text { subject to } \quad & U\lfloor V\rfloor x \leq \hat{d}, \\
& \sum_{j \in I_{M_{R}}} x_{j} \leq 1, \\
& x_{j} \geq 0, \quad \forall j \in I_{M_{R}} .
\end{array}
$$

Let the optimal objective value of PM3 (resp. SM2) be $z^{\text {PM3 }}$ (resp. $z^{\mathrm{SM} 2}$ ). Then, the following properties hold:

Proposition 3.6. $z^{S M 2}=z_{L P}^{S M(d, d)}$
Proof. The proof is similar to the case of Proposition 3.2. To elaborate in detail, let $R_{H}^{W}=\left\{\left\lfloor\hat{r}^{1}\right\rfloor, \ldots,\left\lfloor\hat{r}^{M_{R}}\right\rfloor\right\}$. Note that an element in $R_{H}^{W}$ corresponds to a column vector of $\lfloor V\rfloor$ and $R_{H}^{W} \in R$. For each $i \in I_{M_{R}}$ and $j \in I_{M_{W}},\left\lfloor\hat{r}^{i}\right\rfloor$ is a $M_{W}$-dimensional vector, and $\left\lfloor\hat{r}_{j}^{i}\right\rfloor$ represents how much $j$ th width pattern vector in $\hat{Q}_{W}$ is used within height $H$. For each $i \in I_{M_{W}}$, let $q_{i}$ be the width pattern such that $f\left(\hat{a}^{i}\right)=a_{q_{i}}$. Define
the onto function $g: R_{H}^{W} \rightarrow Q_{H}$ as follows:

$$
g\left(\left\lfloor\hat{r}^{i}\right\rfloor\right)_{k}=\sum_{j \in I_{M_{W}}, t\left(q_{j}\right)=k}\left\lfloor\hat{r}_{j}^{i}\right\rfloor, \quad \forall \hat{r}^{i} \in R_{H}^{W} .
$$

The meaning of the transformation $g$ is that, the transformed vector from $R_{H}^{W}$ describes how strip-defining items of width pattern vectors are ordered vertically within height $H$. Also, since it is possible to pack only a single item in each strip, it is clear that $g$ is an onto function. Lastly, for each $r \in P_{H}(d)$, define $\hat{P}(r)$ as the following:

$$
\hat{P}(r)=\left\{\lfloor\hat{r}\rfloor \in R_{H}^{W} \mid g(\lfloor\hat{r}\rfloor)=b_{r}\right\} .
$$

We then suggest the conversion from the feasible solution $\left(x^{\mathrm{SM}(d, d)}, y^{\mathrm{SM}(d, d)}\right)$ of the LP-relaxation of $\operatorname{SM}(d, d)$ to the feasible solution $x^{\mathrm{SM} 2}$ of SM2 and vice versa. For given $x^{\mathrm{SM} 2}$, the following $\left(x^{\mathrm{SM}(d, d)}, y^{\mathrm{SM}(d, d)}\right)$ is a feasible solution of the LP-relaxation of $\operatorname{SM}(d, d)$ with the same objective value:

$$
y_{r}^{\mathrm{SM}(d, d)}=\sum_{i \in \hat{P}(r)} x_{i}^{\mathrm{SM} 2}, \quad \forall r \in P_{H}(d),
$$

and

$$
x_{q}^{\mathrm{SM}(d, d)}=\sum_{i \in I_{M_{W}}, \hat{a}^{i} \in P(q)}\left(\lfloor V\rfloor x^{\mathrm{SM} 2}\right)_{i}, \quad \forall q \in P_{W} .
$$

Also, it can be verified that $z^{\mathrm{SM} 2} \geq z_{\mathrm{LP}}^{\mathrm{SM}(d, d)}$ since equally distributing the corresponding height and width patterns in instance $\mathbf{I}$ to the patterns in $\hat{\mathbf{I}}$ makes the feasible solution of SM2.

Proposition 3.7. $z_{L P}^{P M 2}=z^{P M 3} \leq 2 z^{S M 2}$

Proof. The proof is similar to the proof of Proposition 3.5. Either a fractional component or the rest components of any element $\hat{r} \in R$ has equal or more than half of the profits generated by $\hat{r}$. Given a feasible solution in PM3, choosing the more profitable part of each element in $R$ constructs a feasible solution in SM2 with equal or more than half of the original objective value.

Theorem 3.8. $z^{*} \leq z_{L P}^{S M(d, d)} \leq z_{L P}^{P M(d)} \leq z_{L P}^{M L} \leq 2 z_{L P}^{P M(d)} \leq 4 z_{L P}^{S M(d, d)}$

Proof. With the results of Proposition 2.1, 3.2, and 3.3, the following inequality is valid:

$$
z^{*} \leq z_{\mathrm{LP}}^{\mathrm{SM}(d, d)} \leq z_{\mathrm{LP}}^{\mathrm{PM}(d)} \leq z_{\mathrm{LP}}^{\mathrm{ML}}
$$

Also, Proposition 3.5, 3.6, and 3.7 prove the rest of the theorem.
The tight example of $z_{\mathrm{LP}}^{\mathrm{ML}} \leq 2 z_{\mathrm{LP}}^{\mathrm{PM}(d)} \leq 4 z_{\mathrm{LP}}^{\mathrm{SM}(d, d)}$ is easily constructed: let the large plate has a (width, height) pair of ( $2 \mathrm{M}, 2 \mathrm{M}$ ) and assume that there are only 4 different types of items sharing the same (width, height) pair ( $M+1, M+1$ ) with unit profit and unit demand. When $M \rightarrow \infty$, then $z_{\mathrm{LP}}^{\mathrm{ML}} \rightarrow 4, z_{\mathrm{LP}}^{\mathrm{PM}(d)} \rightarrow 2$, and $z_{\mathrm{LP}}^{\mathrm{SM}(d, d)}=z^{*}=1$.

### 3.3 Polynomial-size Model

Since all the previous models are not polynomial-size models, verifying the existence of a polynomial-size model for the 2TDK is needed. With the result from Eisenbrand and Shmonin [8] and the structure of $\operatorname{PM}(u)$, it is possible to construct a polynomialsize model. Eisenbrand and Shmonin [8] provides the upper bound on numbers of nonzero components in the optimal solution in integer linear programming problems.

Lemma 3.9. Let $\min \left\{c^{T} y \mid A y \leq b, y \in Z_{+}^{n}\right\}$ be an integer program, where $A \in Z_{+}^{d \times n}$ and $b \in Z_{+}^{n}$. If this integer program has a finite optimum value with $\gamma$, then there exists an optimal value $y^{*} \in Z_{+}^{n}$ with the number of nonzero components of $y^{*}$ at most $\sum_{i=1}^{n} \log _{2}\left(b_{i}+1\right)+\log _{2}(\gamma+1)$.

Proof. As $\min \left\{c^{T} y \mid A y \leq b, y \in \mathbf{Z}_{+}^{n}\right\}=\min \left\{c^{T} y \mid A y+z=b, y \in \mathbf{Z}_{+}^{n}, z \in \mathbf{Z}_{+}^{n}\right\}$, the proof ends by the result of [8].

With this lemma, the following proposition holds:

Proposition 3.10. Let $p_{\max }$ and $d_{\max }$ indicate the maximum value of components in given $p$ and $d$, respectively. Then, there exists an optimal solution in $P M(d)$ with at most $M=\left\lceil\log _{2}(n)+\log _{2}\left(p_{\max }\right)+(n+1) \log _{2}\left(d_{\max }\right)+\log _{2}(H)\right\rceil$ nonzero components. Proof. Using Lemma 3.9, there exists an optimal solution in $\operatorname{PM}(d)$ with at most $\left\lceil n \log _{2}\left(d_{\max }\right)+\log _{2}(H)+\log _{2}\left(n d_{\max } p_{\max }\right)\right\rceil=M$ nonzero components.

Therefore, there exists an optimal solution constructed by a polynomial number of width patterns and a polynomial-size NP certificate. Furthermore, with at most $M$ patterns considered, a nonlinear polynomial-size model for the 2 TDK is easily
found:

$$
\begin{align*}
\operatorname{maximize} & \sum_{i \in I_{M}} \sum_{j \in I_{n}}\left(p_{j} s_{i j}\right) x_{i}  \tag{3.1}\\
\text { subject to } & \sum_{i \in I_{M}} x_{i} s_{i j} \leq d_{j}, \quad \forall j \in I_{n},  \tag{3.2}\\
& \sum_{j \in I_{n}} w_{j} s_{i j} \leq W, \quad \forall i \in I_{M},  \tag{3.3}\\
& \sum_{i \in I_{M}} x_{i} l_{i} \leq H,  \tag{3.4}\\
& s_{i j} \leq d_{j} z_{i j}, \quad \forall i \in I_{M}, j \in I_{n}  \tag{3.5}\\
& l_{i} \geq h_{j} z_{i j}, \quad \forall i \in I_{M}, j \in I_{n}  \tag{3.6}\\
& x \in \mathbf{Z}_{+}^{M}, l \in \mathbf{Z}_{+}^{M}, s \in \mathbf{Z}_{+}^{M \times n}, z \in \mathbf{B}^{M \times n} . \tag{3.7}
\end{align*}
$$

A tuple of decision variables $\left(s_{i 1}, \ldots, s_{i n}\right)$ corresponds to the $i$ th auxiliary width pattern, a decision variable $l_{i}$ denotes the height of the $i$ th auxiliary width pattern, and a decision variable $z_{i j}$ represents the sign of $s_{i j}$. Then, a decision variable $x_{i}$ shows how much $i$ th auxiliary width pattern has been used. With these decision variables, constraints (3.1) represent the nonlinear objective function, and a set of constraints (3.2) corresponds to the demand constraint which is nonlinear. Constraints (3.3) and (3.5) indicate that each pattern defined as the variables $s_{i}$ should be the feasible width pattern, Constraints (3.6) determine the height of the strip, and constraints (3.4) describe the height constraint. Lastly, groups of constraints (3.7) restrain the variables to be integer.

Note that for $i \in I_{M}, s_{i}=\left(s_{i 1}, \ldots, s_{i n}\right)$ corresponds to the temporary width pattern and $l_{i}$ corresponds to the height of its strip-defining item. In addition, since
$s_{i j}, x_{i}$ are bounded by $d_{\max }$ and $l_{i}$ is bounded by $H$, one can represent integer variables as the weighted sum of polynomial-size numbers of binary variables. For example, integer variable $s_{i j}$ can be expressed as the following:

$$
s_{i j}=\sum_{k=1}^{\left\lceil\log _{2}\left(d_{\max }\right)\right\rceil} 2^{k-1} s_{i j k},
$$

where each $s_{i j k}$ is a binary variable. Furthermore, if $x$ and $y$ are two binary variables, then $x y$ can be expressed as the new binary variable $k_{x y}$ satisfying the following inequality:

$$
\begin{equation*}
x+y-1 \leq k_{x y}, \quad k_{x y} \leq x, \quad k_{x y} \leq y \tag{3.8}
\end{equation*}
$$

After converting all the integer variables into the weighted sum of binary variables, we can apply procedure (3.8) for all the nonlinear forms in (3.1), (3.2), and (3.4). Despite its complex structure, this transformation leads to the polynomial-size integer linear formulation. For convenience, let $\hat{D}=\left\lceil\log _{2}\left(d_{\max }\right)\right\rceil$ and $\hat{H}=\left\lceil\log _{2}(H)\right\rceil$. The explicit version of polynomial-size formulation is as follows (for convenience, we do not explicitly mention the range of indices):

$$
\begin{aligned}
\text { POLY : maximize } & \sum_{i=1}^{n} \sum_{m=1}^{M} \sum_{k=1}^{\hat{D}} \sum_{l=1}^{\hat{D}} 2^{k+l-2} p_{i} s_{i k m l} \\
\text { subject to } & \sum_{m=1}^{M} \sum_{k=1}^{\hat{D}} \sum_{l=1}^{\hat{D}} 2^{k+l-2} s_{i k m l} \leq d_{i}, \quad \forall i \\
& \sum_{i=1}^{n} \sum_{k=1}^{\hat{D}} 2^{k-1} w_{i} \bar{q}_{i k}^{m} \leq W, \quad \forall m, \\
& \sum_{m=1}^{M} \sum_{l=1}^{\hat{D}} \sum_{t=1}^{\hat{H}} 2^{l+t-2} r_{m l t} \leq H, \\
& \sum_{k=1}^{\hat{D}} 2^{k-1} \bar{q}_{i k}^{m} \leq d_{i} z_{i}^{m}, \quad \forall i, m, \\
& \bar{q}_{i k}^{m} \leq z_{i}^{m}, \quad \forall i, k, m, \\
& \sum_{t=1}^{\hat{H}} 2^{t-1} \bar{H}_{m t} \geq h_{i} z_{i}^{m}, \quad \forall i, m, \\
& s_{i k m l} \geq \bar{q}_{i k}^{m}+x_{m l}-1, \quad \forall i, k, m, l, \\
& s_{i k m l} \leq \bar{q}_{i k}^{m}, \quad \forall i, k, m, l, \\
& s_{i k m l} \leq x_{m l}, \quad \forall i, k, m, l, \\
& r_{m l t} \geq x_{m l}+\bar{H}{ }_{m t}-1, \quad \forall m, l, t, \\
& r_{m l t} \leq x_{m l}, \quad \forall m, l, t, \\
& r_{m l t} \leq \bar{H}_{m t}, \quad \forall m, l, t, \\
& a l l \text { variables } s, \bar{q}, \bar{H}, r, z \text { are binary. }
\end{aligned}
$$

Although it yields a polynomial-size model, the real usage of this model is not recommended. Detailed results are covered in Chapter 5 .

## Chapter 4

## Exact Methods

Models except POLY are either exponential-size or pseudo-polynomial-size formulations. Pattern-based formulations have an exponential number of patterns, and an arc-flow formulation has variables corresponding to the height and width of the large plate explicitly. Lastly, the size of a level-packing model increases exponentially proportional to the size of the demands of items.

There have been various approaches to deal with large-scale formulations. For example, we usually choose to generate needed columns in each stage in respect of pattern-based formulations. Using column generation technique, Belov and Scheithauer [2] derived a branch-and-cut-and-price algorithm for the 2TDK based on the formulation $\mathrm{PM}(d)$. Also, as not all of constraints (2.21) may be needed, the branch-and-cut approach may be effective. See [6] for general information of solving large-scale mixed integer programs.

In addition, there have been some research which focus on reducing the size of formulations. For instance, Martinovic et al. [21] suggests some techniques to avoid unnecessary variables in one-dimensional cutting stock problems. In this thesis, we focus on the implementation of each exact method.

### 4.1 Branch-and-price Algorithm for the Strip Packing Model

Based on column generation techniques for solving the LP-relaxation, research including [19] summarizes the general methodology and some technical issues about branch-and-price algorithms. Also, Belov and Scheithauer [2] and Lodi and Monaci [18] illustrate the column-generation procedure for the strip packing model.

The main idea of this approach for solving $\operatorname{PM}(d)$ is that we only solve the problem with the restricted set of width patterns, named $P_{W}$ instead of solving $\operatorname{PM}(d)$ with all width patterns in $P_{W}(d)$. Therefore, in column generation approach, we solve the following relaxed problem $\operatorname{RPM}\left(P_{W}\right)$ :

$$
\begin{align*}
\operatorname{RPM}\left(P_{W}\right): \quad \text { maximize } & \sum_{a \in P_{W}} \sum_{i \in I_{n}} p_{i} a_{q i} x_{q}  \tag{4.1}\\
\text { subject to } \quad & \sum_{q \in P_{W}} a_{q i} x_{q} \leq d_{i}, \quad \forall i \in I_{n},  \tag{4.2}\\
& \sum_{q \in P_{W}} h_{t(q)} x_{q} \leq H,  \tag{4.3}\\
& x_{q} \geq 0, \quad \forall q \in P_{W} . \tag{4.4}
\end{align*}
$$

Note that constraints (4.1), 4.2, and (4.3) only involve width patterns in $P_{W}$. Also, as we solve the linear program, a set of constraints (4.4) replaces the integer constraints. To check whether additional width patterns are needed, a slave problem has to be solved. Let $\mu \in \mathbf{R}^{n}$ be the dual variables of the demand constraints 4.2 ) and $\nu$ be the dual variable of the height constraint 4.3). If the optimal objective value of the following subproblem $\operatorname{SPM}(j, \mu)$ is above $\nu * h_{j}$ for some $j \in I_{n}$, create
the new width pattern defined by the optimal values of $a$ in $\operatorname{SPM}(j, \mu)$.

$$
\begin{align*}
& \operatorname{SPM}(j, \mu): \quad \max \sum_{i \in I_{n}}\left(p_{i}-\mu_{i}\right) a_{i}  \tag{4.5}\\
& \text { subject to } a_{i} \leq d_{i}, \quad \forall i \in I_{n},  \tag{4.6}\\
& \sum_{i \in I_{n}} w_{i} a_{i} \leq W,  \tag{4.7}\\
& a_{i}=0, \quad \forall i \in I_{j-1},  \tag{4.8}\\
& a_{j} \geq 1,  \tag{4.9}\\
& a_{i} \in \mathbf{Z}_{+}, \quad \forall i \in I_{n} . \tag{4.10}
\end{align*}
$$

The objective function (4.5) represents reduced costs, a set of constraints 4.6 restricts the pattern to satisfy the demand constraint, a constraint 4.7) makes the pattern to meet the width constraint, constraints 4.8 and 4.9) indicate that the subproblem is correlated with finding the width pattern with strip-defining item type $j$, and constraints 4.10) restrain the pattern vector to be integral. Then, whenever the optimal objective value of $\operatorname{SPM}(j, \mu)$ is above $\nu * h_{j}$, add the corresponding width pattern to $P_{W}$. Until there is no additional width pattern to be generated, solve $\operatorname{RPM}\left(P_{W}\right)$ and $\operatorname{SPM}(j, \mu)$ iteratively. After this procedure, it is convinced that the optimal objective value of $\operatorname{RPM}\left(P_{W}\right)$ becomes the LP-relaxation value of $\operatorname{PM}(d)$.

Combining the column generation procedure with a branch-and-bound methodology yields a branch-and-price algorithm. After solving $\operatorname{RPM}\left(P_{W}\right)$ completely (i.e., no additional patterns are needed, if optimal solution $x^{*} \in \mathbf{R}^{\left|P_{W}\right|}$ is integral, it becomes the optimal solution of $\operatorname{PM}(d)$. However, if there exists any $q_{F} \in P_{W}$ such that $x_{q_{F}}^{*}$ has a fractional value, then we need to branch the node into two child nodes:
a left child with additional constraint that $x_{q_{F}} \leq\left\lfloor x_{q_{F}}^{*}\right\rfloor$ and a right child with additional constraint that $x_{q_{F}} \geq\left\lfloor x_{q_{F}}^{*}\right\rfloor+1$. See Figure 4.1 for a simple illustration of branching procedure.

Figure 4.1: Branching strategy (variable dichotomy).

Then, an additional constraint that excludes the width pattern $q_{F}$ to be generated again when solving the subproblem should be added to a left child node and child nodes of the left child node. Then, the following constraint should be added to $\operatorname{SPM}\left(t\left(q_{F}\right), \mu\right)$ of a left child node and child nodes of it:

$$
\begin{equation*}
a \neq a_{q_{F}} . \tag{4.11}
\end{equation*}
$$

To express a constraint 4.11) as a linear constraint, we choose to transform each variable $a_{i}$ in $\operatorname{SPM}(j, \mu)$ for any $i, j \in I_{n}$ into the weighted sum of binary variables $a_{i 1}^{B}, \ldots, a_{i \hat{D}}^{B}$ so that $a_{i}=\sum_{k \in I_{\hat{D}}} 2^{k-1} a_{i k}^{B}$. Then, the subproblem $\operatorname{SPM}(j, \mu)$ can be represented as the following problem $\mathrm{SP}(j, \mu)$ :

$$
\begin{aligned}
& \mathrm{SP}(j, \mu): \text { maximize } \sum_{i \in I_{n}}\left(p_{i}-\mu_{i}\right) a_{i} \\
& \text { subject to } \quad a_{i} \leq d_{i}, \quad \forall i \in I_{n}, \\
& \sum_{i \in I_{n}} w_{i} a_{i} \leq W \\
& a_{i}=0, \quad \forall i \in I_{j-1}, \\
& a_{j} \geq 1, \\
& a_{i}=\sum_{k \in I_{\hat{D}}} 2^{k-1} a_{i k}^{B}, \quad \forall i \in I_{n} \\
& a_{i k}^{B} \in \mathbf{B}, \quad \forall i \in I_{n}, \quad \forall k \in I_{\hat{D}} .
\end{aligned}
$$

For $q_{F} \in Q_{W}$, there exists a unique binary vector $a_{q_{F}}^{B}=\left(a_{q_{F} 11}^{B}, \ldots, a_{q_{F} n \hat{D}}^{B}\right)$ such that $a_{q_{F} i}=\sum_{k \in I_{\hat{D}}} 2^{k-1} a_{q_{F} i k}^{B}$. Then, 4.11 corresponds to the following inequality:

$$
\begin{equation*}
\mathrm{NG}\left(q_{F}\right):=\sum_{i \in I_{n}, k \in I_{\hat{D}}, a_{q_{F}}^{B}=1}\left(a_{q_{F} i k}^{B}-a_{i k}^{B}\right)+\sum_{i \in I_{n}, k \in I_{\hat{D}}, a_{q_{F}}^{B}=0}\left(a_{i k}^{B}-a_{q_{F} i k}^{B}\right) \geq 1 . \tag{4.12}
\end{equation*}
$$

Note that inequality 4.12) changes the structure of the problem. Both $\operatorname{SP}(j, \mu)$ and $\operatorname{SPM}(j, \mu)$ are knapsack problems, but adding inequality 4.12) complexes the problem.

We solve the subproblem by a solver offered by Xpress [9, and the best-bound strategy is selected as a search strategy. Also, we initialize $P_{W}$ as the standard basis of $\mathbf{R}^{n}$. As a way to obtain decent lower bounds, we devise a simple heuristic that
solves an instance to optimality only using width patterns generated in the root node by the branch-and-bound method: i.e., solving $\operatorname{RPM}\left(P_{W}\right)$ to optimality. Besides, we make an effort to improve the lower bound by rounding down the fractional solution at each node. The overall procedure is summarized in Algorithm 1 .

```
Algorithm 1 A branch-and-price algorithm for \(\operatorname{PM}(d)\).
    Input: An instance of the 2TDK
    Initialize \(P_{W}\);
    Solve \(\operatorname{RPM}\left(P_{W}\right)\) by the column generation method and get the optimal solution
    \(x^{*}\) and its optimal objective value \(U B\);
    if \(x^{*}\) is integral then
        return \(U B\);
    else
        Split the root node into two child nodes by the fractional component of \(x^{*}\);
        Solve \(\operatorname{RPM}\left(P_{W}\right)\) to optimality and save the optimal objective value as \(L B\);
        \(n d \leftarrow 2\);
        while \(L B+1>U B\) or \(n d=0\) do
            Select the unsolved node whose parent node has a value of \(U B\);
            Solve the selected node.
            if The selected node is feasible then
                Get the optimal solution \(x_{N}^{*}\) and its objective value \(U B_{N}\) of the node;
                if \(x_{N}^{*}\) is integral then
                        if \(L B<U B_{N}\) then
                        \(L B \leftarrow U B_{N}\).
                end if
                else
                Split the selected node into two child nodes;
                \(n d \leftarrow n d+2\);
                Update LB with rounding down the incumbent solution if possible;
                end if
            end if
            Update \(U B\) from the branch-and-bound tree;
            \(n d \leftarrow n d-1 ;\)
        end while
        return \(L B\);
    end if
```

### 4.2 Branch-and-price Algorithm for the Staged-pattern Model

The overall structure of the branch-and-price scheme based on $\operatorname{SM}(d, d)$ is similar to that of $\operatorname{PM}(d)$ except for height pattern generation. To bolster the lower bound, we use the same heuristic devised for solving $\operatorname{PM}(d)$. Note that, for staged-pattern models, it is uncertain that all height patterns are generated at the root node. Therefore, even for staged-pattern models, we only utilize width patterns to construct $\operatorname{RPM}\left(P_{W}\right)$ and solve it through the branch-and-bound procedure. We propose two branch-and-price algorithms for the staged-pattern formulation: the standard scheme and the height-aggregated scheme.

### 4.2.1 The Standard Scheme

With restricted pattern set $P_{W} \in P_{W}(d)$ and $P_{H} \in P_{H}(d)$, let $\mu \in \mathbf{R}^{n}$ be the dual variable corresponding to the constraints (2.1), $v \in \mathbf{R}^{n}$ be the dual variable of the constraints (2.2), and $\nu$ be the dual variable of the constraint (2.3), respectively. To determine whether we need either additional height pattern or width pattern, we need to solve the $n+1$ subproblems $\operatorname{SPM}(j, \mu)$ for all $j \in I_{n}$ and a subproblem $\operatorname{HPM}(\mu)$, which is defined as follows:

$$
\begin{align*}
& \operatorname{HPM}(v): \max  \tag{4.13}\\
& \quad \sum_{i \in I_{n}} v_{i} b_{i}  \tag{4.14}\\
& \text { subject to } b_{i} \leq d_{i}, \quad \forall i \in I_{n},  \tag{4.15}\\
& \sum_{i \in I_{n}} h_{i} b_{i} \leq H,  \tag{4.16}\\
& b_{i} \in \mathbf{Z}_{+}, \quad \forall i \in I_{n} .
\end{align*}
$$

Note that 4.13), 4.14, 4.15 , and 4.16 makes the formulation as the bounded knapsack problem. If the objective value of $\operatorname{SPM}(j, \mu)$ is above $v(j)$ for some $j \in$ $I_{n}$, add the corresponding width pattern to $P_{W}$. If the objective value of $\operatorname{HPM}(v)$ is above $\nu$, add the corresponding height pattern to $P_{H}$. If any width pattern or height pattern is no more generated, it is convinced that we solve the LP-relaxation of $\operatorname{SM}(d, d)$. Let $x^{*}$ and $y^{*}$ be the optimal solution after this column generation procedure. If $x^{*}$ is integral, then it is convinced that we solve $\operatorname{SM}(d, d)$ exactly as a set of constraints (2.4) can be relaxed.

If there exists $q_{F} \in P_{W}$ such that $x_{q_{F}}^{*}$ is fractional, we branch the problem as shown in Figure 4.1. For the left child node, inequality $N G\left(q_{F}\right)$ should be added to the subproblem $\operatorname{SP}\left(t\left(q_{F}\right), \mu\right)$.

### 4.2.2 The Height-aggregated Scheme

In this scheme, we take advantage of SM-HA, which uses a minimal representation of height patterns. Denote the dual variable corresponding to the constraints (2.7), (2.8), and 2.9) by $\mu \in \mathbf{R}^{m}, v \in \mathbf{R}^{M}$, and $\nu \in \mathbf{R}$, respectively. To solve the

LP-relaxation of SM-HA by the column-generation procedure, $m+1$ subproblems $\operatorname{SPM} 2(j, \mu)$ for $j \in I_{m}$, and $\operatorname{HPM} 2(\nu)$ have to be solved to determine whether an additional width or height pattern is needed. $\operatorname{SPM} 2(j, \mu)$ and $\operatorname{HPM} 2(\nu)$ are defined as follows:

$$
\begin{aligned}
& \operatorname{SPM} 2(j, \mu): \quad \text { maximize } \sum_{i \in I_{n}}\left(p_{i}-\mu_{i}\right) a_{i} \\
& \text { subject to } \quad a_{i} \leq d_{i}, \quad \forall i \in I_{n}, \\
& \sum_{i \in I_{n}} w_{i} a_{i} \leq W, \\
& a_{i}=0, \quad \forall i \in I_{n} \text { such that } h_{i}>h_{(j)}, \\
& \sum_{i \in I_{n}, h_{i}=h_{(j)}} a_{i} \geq 1, \\
& a_{i} \in \mathbf{Z}_{+}, \quad \forall i \in I_{n},
\end{aligned}
$$

and

$$
\begin{aligned}
& \operatorname{HPM} 2(v): \text { maximize } \\
& \sum_{i \in I_{m}} v_{i} b_{i} \\
& \text { subject to } \quad b_{i} \leq \sum_{j \in I_{n}, h_{j}=h_{(i)}} d_{j}, \quad \forall i \in I_{m}, \\
& \sum_{i \in I_{m}} h_{(i)} b_{i} \leq H, \\
& b_{i} \in \mathbf{Z}_{+}, \quad \forall i \in I_{m} .
\end{aligned}
$$

In the aspect of the branch-and-price algorithm, it is similar to the case of the standard scheme that we branch the nodes by the fractional part of width pattern
usage, and (4.12) is added to the subproblem of the left child node. Although its LP-relaxation value is weaker than the LP-relaxation value of $\operatorname{SM}(d, d)$, it requires solving $m+1$ subproblems at each iteration, and there is more freedom on selecting height pattern.

Furthermore, since the subproblem $\operatorname{HPM}(v)$ is a knapsack problem, for $i_{1}$ and $i_{2} \in I_{n}$ such that $h_{i_{1}}=h_{i_{2}}$, the solution does not tend to choose both $b_{i_{1}}$ and $b_{i_{2}}$. Therefore, some height-patterns that include various item types are relatively difficult to be generated. However, this phenomenon does not happen to the case of HPM2 $(v)$ since we only need to consider the summation of $b_{i_{1}}+b_{i_{2}}$. Therefore, we expect computational efficiency for the branch-and-price algorithm for SM-HA, which we discuss in Chapter 5 .

We end up this subsection with the overall branch-and-price procedure for the staged-pattern models, as summarized in Algorithm 2. We present a pseudocode for the standard scheme since the two proposed schemes share a similar structure.

```
Algorithm 2 A branch-and-price algorithm for the staged-pattern models.
    Input: An instance of the 2TDK
    Initialize \(P_{W}\) and \(P_{H}\);
    Solve the LP-relaxation of the restricted master problem by the column generation
    method and get the optimal solution \(\left(x^{*}, y^{*}\right)\) and its optimal objective value \(U B\);
    if \(x^{*}\) is integral then
        return \(U B\);
    else
        Split the root node into two child nodes by the fractional component of \(x^{*}\);
        Construct \(\operatorname{RPM}\left(P_{W}\right)\) with width patterns at the root node;
        Solve \(\operatorname{RPM}\left(P_{W}\right)\) to optimality, and save the optimal objective value as \(L B\);
        \(n d \leftarrow 2\);
        while \(L B+1>U B\) or \(n d=0\) do
            Select the unsolved node whose parent node has a value of \(U B\);
            Solve the selected node.
            if The selected node is feasible then
                Get the optimal solution \(x_{N}^{*}\) and its objective value \(U B_{N}\) of the node;
                if \(x_{N}^{*}\) is integral then
                        if \(L B<U B_{N}\) then
                        \(L B \leftarrow U B_{N}\).
                        end if
                else
                                    Split the selected node into two child nodes;
                                    \(n d \leftarrow n d+2\);
                                    Update LB with rounding down the incumbent solution if possible;
                end if
            end if
            Update \(U B\) from the branch-and-bound tree;
            \(n d \leftarrow n d-1\);
        end while
        return \(L B\);
    end if
```

### 4.3 Branch-and-cut Algorithm for the Modified Level Packing Model

Although general solvers such as Xpress [9] can handle both LM and ML for instances with small $N$, more elaborate implementation should be considered for instances with large $N$. Furthermore, the number of inequalities (2.21) that we add to the formulation LM is about $\mathcal{O}\left(N^{2}\right)$, which can be computationally burdensome. Therefore, we devise a branch-and-cut algorithm (i.e., delayed constraint generation) for ML since not all inequalities may be needed to solve the problem exactly. To elaborate in detail, with a basic branch-and-bound scheme applied to LM, whenever we solve the LP-relaxation of each node, we check whether there exist some $k \in I_{N}$ and $j \in\{k+1, \ldots, N\}$ such that $x_{j k}>x_{k k}$. Then, we add violated inequalities $x_{j k} \leq x_{k k}$ to the formulation until we end up the branch-and-bound procedure. Only for solving the root node, we solve the node iteratively until no violated inequalities are found. For other nodes, we add violated inequalities only for once. The overall branch-and-cut procedure is summarized in Algorithm 3.

We also add groups of valid inequalities of LM suggested by Lodi and Monaci [18] to reduce symmetry when solving the problem. In this thesis, computational experiments for ML are implemented using the branch-and-cut algorithm.

```
Algorithm 3 A branch-and-cut algorithm for the modified-level packing model.
    Input: An instance of the 2TDK
    Solve the LP-relaxation of LM in each node and get the optimal solution \(x^{*}\);
    if the node is the root node then
        while \(x^{*}\) does not violate any of inequalities (2.21) do
            For all \(k \in I_{N}\) and \(j \in\{k+1, \ldots, N\}\), search all \(x_{j k}^{*}\) such that \(x_{j k}>x_{k k}\);
            Add corresponding inequalities \(x_{j k} \leq x_{k k}\) to the formulation;
            Repeat solving the root node;
        end while
    else
        if there remains unsolved nodes or \(x^{*}\) is not integral then
            For all \(k \in I_{N}\) and \(j \in\{k+1, \ldots, N\}\), search all \(x_{j k}^{*}\) such that \(x_{j k}>x_{k k}\);
            Add corresponding inequalities \(x_{j k} \leq x_{k k}\) to the formulation;
            Branch the node by the fractional variable if possible;
            Solve the next node.
        else
            Terminate the branch-and-bound procedure.
        end if
    end if
    return the optimal objective value;
```

## Chapter 5

## Computational Experiments

We conduct computational experiments to observe the undiscovered tendency of each model in its real usage. In this thesis, we conduct experiments using the solvers offered by Xpress 8.9 [9 with $\operatorname{Intel}(\mathrm{R})$ Core(TM) i7-4770 CPU @ 3.10 GHz and 16GB of RAM. The running time for solving an instance was limited to 600 s .

### 5.1 Instances

We divide the well-known instance set proposed by Hifi and Roucairol [15] into two groups: a group of (relatively) small instances and a group of large instances. A group of small instances consists of 16 instances, and a group of large instances is composed of 20 instances. Each of the group is summarized in Table 5.1 and 5.2, respectively. In Table 5.1 and 5.2, the headings $w_{\min }$ and $w_{\max }$ are defined as $\min _{i \in I_{n}} w_{i}$ and $\max _{i \in I_{n}} w_{i}$, respectively. $h_{\min }\left(h_{\max }\right)$ and $d_{\min }\left(d_{\max }\right)$ are defined in the same way. The known optimal objective value of each instance is presented with the heading OPT. Optimal objective values of instances that we failed to solve to optimality in this thesis are obtained from the computational result of Alvarez-Valdes et al. [1].

Table 5.1: Summary of small instances.

| Name | n | W | H | $w_{\min }$ | $w_{\max }$ | $h_{\min }$ | $h_{\max }$ | $d_{\min }$ | $d_{\max }$ | OPT |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |

One of the classes of artificial instances proposed by Berkey and Wang (1987) [3] is also used to check the performance of each model when $d_{\max }$ changes. We focus on Class 5 whose instance is defined as $(n, 100,100, h, w, d, p)$ with $n$ taking a value among $\{20,40,60,80,100\}, w_{i} \sim U(1,100), h_{i} \sim U(1,100), d_{i}=1$, and $p_{i}=h_{i} * w_{i}$ for $i \in I_{n}$, where $U$ describes the discrete uniform distribution. We generated 10 instances per each $n \in\{20,40,60,80,100\}$.

Then, we changed demands of instances in Class 5 and analyze the impact on the overall performance of each model. For a given instance, we set the demand for each item the value $\Delta$ (i.e., $d_{i}=\Delta$ for all $i \in I_{n}$ ). Four different values of $\Delta$ are used: $1,3,5$, and 7 . As other information such as heights and widths is unchanged, an increase in $\Delta$ affects solving the instance to optimality in two ways: the first effect is that the problem becomes easier in a sense that the problem is getting similar to the unconstrained case, and the second effect is that the problem gets difficult as there are much more options for items to choose.

### 5.2 Upper Bounds Comparison

The objectives of this section are to reveal the answers to the following questions:
(a) How much the LP-relaxation values of models follow the Theorem 3.8 in a real situation?
(b) How are the qualities of the LP-relaxation values for various models?
(c) How effective is the only polynomial-size model POLY in the aspect of finding a solution?

### 5.2.1 A Group of Small Instances

The LP-relaxation values and time (seconds) consumed for solving the LP-relaxation of models in Chapter 2 are reported in Table 5.3. The headings for the LP-relaxation values and time are $\mathbf{L P}$ and $t_{\mathbf{L P}}$, respectively. We also compute the LP gap defined as the follows:

$$
\text { LP gap }=\frac{(\text { LP-relaxation value })-(\text { Optimal objective value })}{(\text { Optimal objective value })} \times 100(\%)
$$

Optimal objective values for a group of small instances are obtained from the result of subsection. We summarize LP gaps in Table 5.4 and Figure 5.1. We exclude the average LP gap of POLY in 5.1 since it shows the average LP gap of over 500 (\%). In figures in this chapter, PM and SM stand for $\operatorname{PM}(d)$ and $\mathrm{SM}(d, d)$, respectively.
Table 5.3: Time costs and the LP-relaxation valuse for small instances.

| Instance | AF |  | POLY |  | LM |  | ML |  | $\operatorname{PM}(d)$ |  | $\mathrm{SM}(d, d)$ |  | SM-HA |  |

Figure 5.1: Average LP gaps for small instances.

Interestingly, $z_{\mathrm{LP}}^{\mathrm{AF}}$ is less than $z_{\mathrm{LP}}^{\mathrm{PM}(d)}$ in some instances such as $3,3 \mathrm{~s}$, and A 1 s , while the relationship is reversed in other instances. Since $z_{\mathrm{LP}}^{\mathrm{AF}}=z_{\mathrm{LP}}^{\mathrm{SM}(\infty, \infty)}, z_{\mathrm{LP}}^{\mathrm{SM}(\infty, \infty)}$ and $z_{\mathrm{LP}}^{\mathrm{PM}(d)}$ are incomparable.

Although POLY costs the largest amount of time to compute the LP-relaxation values, its LP gaps are the worst. Then, AF seems to spend more time when $H$ and $W$ of an instance are relatively large. For level packing models, LM shows the fastest speed to compute the LP-relaxation values, and ML could enhance the LP-relaxation values with a small sacrifice on time. Pattern-based models generally require more time and level packing models for computing the LP-relaxation values, but LP gaps of pattern-based models are impressive. Especially, staged-pattern models sometimes offer the exact solution by solving only the root node.

To verify sizes of formulations, we summarize the numbers of variables and constraints of AF, POLY, and level packing models in Table 5.5. For pattern-based models, as we implement them by column generation, numbers of generated width patterns and height patterns ((WP_Root for width patterns and HP_Root for height patterns) are reported in Table 5.6. As shown in Table 5.5, AF and POLY show relatively large sizes of formulations. The compactness of level packing models is remarkable since POLY is a polynomial-size model, whereas level packing models are not.

Also, except for the instance A4, staged-pattern models generate more width patterns than a strip packing model. Because staged-pattern models can generate at most one height pattern at each iteration, it is plausible that they need much more time to compute the LP-relaxation values than the strip packing model.

Lastly, we compare the ratio of the LP-relaxation values of $\mathrm{ML}, \operatorname{PM}(d)$, and $\operatorname{SM}(d, d)$. In Chapter 3, we theoretically proved that the ratio of $z_{\mathrm{LP}}^{\mathrm{ML}} / z_{\mathrm{LP}}^{\mathrm{PM}(d)}\left(\frac{\mathrm{ML}}{\mathrm{PM}(d)}\right)$ and $z_{\mathrm{LP}}^{\mathrm{ML}} / z_{\mathrm{LP}}^{\mathrm{SM}(d, d)}\left(\frac{\mathrm{ML}}{\operatorname{SM}(d, d)}\right)$ can be at most 2 and 4 , respectively. For each instance in this set of instances, we summarize the ratios in Table 5.7. We verify that the ratios are far from the theoretical result in Theorem 3.8. Therefore, the LP-relaxations values of ML, $\mathrm{PM}(d)$, and $\mathrm{SM}(d, d)$ are much closer than we expected theoretically.

### 5.2.2 A Group of Large Instances

As in the previous subsection, we report the LP-relaxation values, time consumed for solving the LP-relaxation of each model, and LP gaps. Using a simplex method to solve the LP-relaxation of POLY did not succeed in any case within 600 s . On the other hand, solving the LP-relaxation of AF worked for some instances. Since the sizes of both LP relaxations of AF and POLY are too large and sparse, we applied the barrier method to solve them. The overall result of AF and POLY is reported in Table 5.8. We denote the case that exceeds the time limit by TL.
Table 5.8: Summary of the result of AF and POLY for large instances.

| Instance | AF |  |  |  |  |  | POLY |  |  |  |  |

Since the number of variables and constraints of POLY is plentiful, even solving the LP-relaxation of POLY by the barrier method took a large amount of time. Also, the upper bounds provided by the LP-relaxation of POLY is meaningless. Therefore, albeit its theoretical polynomial-size formulation, solving problems using POLY is not preferable. On the other hand, AF shows a better result when using the barrier method. Although the number of variables is large, the sparsity of the overall structure may be favorable to the barrier method.

The general performance of each model is reported in Table 5.9, and the average LP gaps are illustrated in Figure 5.2. In the case of level packing models, sizes of their formulations are much smaller than them of AF and POLY, which leads to fewer time costs for solving their LP relaxations. The number of variables and constraints of level packing models are summarized in Table 5.10. Solving the LP relaxation of LM was the fastest on average, and its compact formulation may contribute to this result. Besides, although ML could provide a better quality of lower bounds, overhead from adding violated inequalities seems not negligible. As shown in Table 5.10, hundreds of cuts were found and added to its formulation.

Generally, ML was dominated by the outcome of $\operatorname{PM}(d)$ since the average time cost and LP gap of $\operatorname{PM}(d)$ outweigh them of $\operatorname{ML} \cdot \operatorname{PM}(d)$ shows the fastest computational cost among pattern-based models, but staged-pattern models are more favorable for their strengths of upper bounds as they sometimes guarantee the optimal objective values. Also, SM-HA proved to improve the column generation process for staged-pattern models with little sacrifice on the LP-relaxation values.

| ATP49 | 7,140 | 403 |  | 7,140 | 459 |

Then, we compare the numbers of generated patterns when solving the LPrelaxations of pattern-based models in Table 5.11. $\mathrm{SM}(d, d)$ generated 45 (\%) more width patterns than $\mathrm{PM}(d)$ in average. SM-HA could reduce its computational time by less generating height patterns. As LP gaps of SM and SM-HA are almost the same, SM-HA seems to produce height patterns more efficiently.

Table 5.11: The number of generated patterns for large instances.

|  | PM $(d)$ |  |  | SM $(d, d)$ |  |  | SM-HA |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | :---: |
| Instance | WP_Root |  | WP_Root | HP_Root |  | WP_Root | HP_Root |  |

| ATP47 | 86 | 141 | 134 |  | 129 | 131 |  |  |
| ATP48 | 68 | 95 | 107 |  | 94 | 81 |  |  |
| ATP49 | 52 | 70 | 67 |  | 71 | 74 |  |  |

Lastly, we compute the relative ratios of the LP-relaxation values between ML, $\operatorname{PM}(d)$, and $\operatorname{SM}(d, d)$. The result is in Table 5.12. As shown in Table 5.7 and 5.12 , the result from Theorem 3.8 seems rather theoretical.

Table 5.12: The LP-relaxation values ratio for large instances.

| Instance | $\frac{\mathrm{ML}}{\mathrm{PM}(d)}$ | $\frac{\mathrm{ML}}{\mathrm{SM}(d, d)}$ |
| :---: | :---: | :---: |
| ATP30 | 1.001 | 1.005 |
| ATP31 | 1.001 | 1.005 |
| ATP32 | 1.004 | 1.005 |
| ATP33 | 1.005 | 1.006 |

| ATP35 | 1.009 | 1.010 |
| ATP36 | 1.007 | 1.012 |
| ATP37 | 1.005 | 1.008 |
| ATP38 | 1.009 | 1.009 |
| ATP39 | 1.003 | 1.011 |
| ATP40 | 1.057 | 1.064 |
| ATP41 | 1.042 | 1.058 |
| ATP42 | 1.023 | 1.028 |
| ATP43 | 1.032 | 1.043 |
| ATP44 | 1.033 | 1.061 |
| ATP45 | 1.043 | 1.044 |
| ATP46 | 1.040 | 1.056 |
| ATP47 | 1.044 | 1.087 |
| ATP48 | 1.039 | 1.046 |
| ATP49 | 1.067 | 1.078 |
| Average | 1.024 | 1.033 |

To conclude, level packing models can solve their LP-relaxation models quickly, but the LP-relaxation values are more credible in the case of pattern-based models. More elaborate algorithms should be constructed in order to utilize AF or POLY computationally.

### 5.2.3 Class 5 Instances

In this subsection, we analyze how the performances of various models would change when the overall demand changes. Since we could get all the optimal values of this set of instances using SM-HA, LP gaps could be computed. The average time and the average LP gap are reported in Table 5.13.
Table 5.13: Average time costs and LP gaps for Class 5.

| $\Delta$ | n | AF |  | LM |  | ML |  | $\operatorname{PM}(d)$ |  | $\operatorname{SM}(d, d)$ |  | SM-HA |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

In this set of instances, because the profit of each item is set to be the area of the item, we get the trivial upper bound $W * H=10000$. It is interesting that except for the case of $\Delta=1$ and $n=20$, all the LP-relaxation values of LM were equal to 10000 . LP gaps of level packing models are relatively high, and the effect of additional inequalities (2.21) was minute. Also, we were able to solve the LPrelaxation of AF by the simplex method due to small $H$ and $W$, and the result shows that LP-relaxation values of AF and pattern-based models are much credible than level packing models. Especially, in the case of $\Delta=1$ and $n=80$, the LPrelaxation values of $\operatorname{SM}(d, d)$ were all as same as optimal objective values.

Table 5.14: The number of variables and constraints for Class 5.

|  |  | AF |  |  | LM |  |  | ML |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| $\Delta$ | n | Variables | Constraints |  | Variables | Constraints |  | Variables | Constraints |

| 7 | 80 | 168,856 | 8,341 |  | 157,080 | 1,119 |  | 157,080 | 1,119 |
| 7 | 100 | 271,346 | 10,401 |  | 245,350 | 1,399 |  | 245,350 | 1,399 |

Even though AF does not use a column generation method, the amount of time
to obtain the LP-relaxation values of AF was most demanding. In order to delineate this phenomenon, we suspect that the size of AF may yield this result. This doubt turns out to be valid, as shown in Table 5.14

Level packing models seem very compact when $\Delta$ is low, but the number of their variables becomes closer to the number of variables in AF when $\Delta$ increases. Therefore, the time cost of level packing models cannot but exceed the time cost for the strip packing model for large $\Delta$. On the other hand, the time costs for pattern-based models show dependency on $n$, rather than $\Delta$. To bolster this opinion, we summarized the number of patterns generated at the root node of pattern-based models at Table 5.15. Note that the numbers of generated patterns are also dependent on $n$.

Table 5.15: The number of patterns generated at the root node for Class 5.

|  |  | PM $(d)$ |  |  | SM $(d, d)$ |  |  |  | SM-HA |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | :---: |

### 5.3 Solving Instances to Optimality

The purpose of this section is to address issues when solving problems using commercial solvers and to verify the effectiveness of exact methods provided in Chapter 4. The running time for each instance was limited to 600 s per instance.

### 5.3.1 A Group of Small Instances

The best lower bound obtained by the feasible solution within the time limit is recorded as Sol. Time (seconds) consumed for solving the instance exactly (Time), and the number of nodes in a branching tree are reported for each model in Table 5.16 and 5.17 . We denote the case that exceeds the time limit by TL. For patternbased models, the numbers of generated width patterns and height patterns are reported as WP and HP, respectively.

Although adding (2.21) yields the tighter LP-relaxation bounds, the total running time of it does not prove effectiveness. The overhead of adding inequalities seems to outweigh its gain on exactitude. It is also interesting that sometimes ML requires a larger number of nodes than LM in spite of its additional inequalities. However, both level packing models show excellence solving problems of small sizes.

AF seems to be unstable in respect of time costs and nodes so that it is difficult to certain whether it will solve a problem quickly. Fortunately, the best lower bounds of AF are all as same as the optimal objective values, whereas the best lower bounds of $\operatorname{PM}(d)$ are not always equivalent to the optimal objective values.

A trial to solve problems using POLY is not recommendable since it failed to solve any small instance to optimality within 600 s . Even with computing lots of nodes, its best lower bounds are approximately 10 percent lower than optimal objective
values.
For pattern-based models, it was not sufficient for the height-aggregated scheme to prove its efficiency in time costs and nodes. Instead, in the aspect of the numbers of generated height patterns and width patterns, SM-HA shows outstanding performance. Generally, staged-pattern models produced smaller numbers of width patterns than the strip packing model, which is opposite to the result at the root node.
Table 5.16: Summary of the result of non-pattern-based models for small instances.

| Instance | AF |  |  | POLY |  |  | LM |  |  | ML |  |  |

### 5.3.2 A Group of Large Instances

As Table 5.8 indicates that solving instances to optimality using AF and POLY seems reckless for large instances, we only provide results of level packing models and pattern-based models in Table 5.18 and 5.19, respectively.

Almost all of the instances were not solved to optimality by level packing models within 600 s . Comparing the number of nodes solved by LM and ML, ML failed to solve as many nodes as LM did since the overhead for checking violated inequalities was not minute.

As shown in Table 5.19, staged-pattern models seem to be the most eminent approach to solve large instances than any other models. However, there exist some instances that even staged-pattern models failed to solve to optimality. Within stagedpattern models, SM-HA is superior than $\operatorname{SM}(d, d)$ in the aspect of time costs. SM-HA can solve 30 percent more quickly than $\operatorname{SM}(d, d)$ for instances that were solved to optimality. The smaller number of generated height patterns may contribute to this result.

In the respect of height patterns, the number of width patterns generated in the strip packing model outweighed it in the staged-pattern models. Although the performance of $\operatorname{PM}(d)$ is dominated by the performance of staged-pattern models, it is comparable to the performance of level packing models. We could conclude that there is a certain type of instance that is favorable to level packing models but not to the strip packing model since instances which LM solved to optimality were different from instances which $\operatorname{PM}(d)$ solved to optimality.

To compare the quality of the best solution found within the time limit, we define the IP gap as follows:

$$
\text { IP gap }=\frac{(\text { Optimal objective value })-(\text { Best Lower Bound })}{(\text { Optimal objective value })} \times 100(\%)
$$

IP gaps for each model are summarized in Table 5.20. Although LM and ML seem to guarantee the decent quality of best solutions found, almost all of the best solutions found by pattern-based models offered the same values as the optimal objective values. This outcome shows the strength of pattern-based models in solving large instances.

Table 5.20: IP gaps for large instances.

### 5.3.3 Class 5 Instances

The number of instances solved to optimality by level packing models within the time limit of 600 s are recorded in Figure 5.3 and 5.4 . As $N$ increases, the number of solved instances by level packing models decreases. Although ML requires some overheads to solve the problem, sometimes it could prove optimality better than LM. However, both level packing models seem to be substantially affected by the increase of $\Delta$.

Figure 5.3: The number of solved instances by LM for Class 5.

Figure 5.4: The number of solved instances by ML for Class 5.

Then, we report the result of AF and $\mathrm{PM}(d)$ in Figure 5.5 and 5.6, respectively. The result of AF was unexpected since the time cost for solving its LP-relaxation for other benchmark instances used to be relatively large. Even without an elaborate variable reduction technique or the branching strategy, AF could prove its effectiveness in solving a fixed, small size of instances. However, $\operatorname{PM}(d)$, which requires the cheapest time cost for solving the LP-relaxation among pattern-based models, sometimes failed to solve instances to optimality even for small $N$. Although $\operatorname{PM}(d)$
did not completely solve all instances to optimality, its performance was robust to $\Delta$. Instead, $\operatorname{PM}(d)$ shows more dependence on $n$. Another characteristic of the result of $\operatorname{PM}(d)$ is that the graph seems to have a $V$-formation pattern for fixed $\Delta$. One hypothesis to explain this tendency is that $\operatorname{PM}(d)$ may be effective in solving the unconstrained instances that resemble instances with large $\Delta$. On the other hand, no such tendency has been found in Figure 5.3.

Figure 5.5: The number of solved instances by AF for Class 5.

Figure 5.6: The number of solved instances by $\operatorname{PM}(d)$ for Class 5 .

In the aspect of staged-pattern models, they were able to solve all instances
within 600 s . With analyzing the average time for computation illustrated in Figure 5.7 and 5.8 , staged-pattern models seem to need more time to solve problems to optimality when $n$ increases. Besides, higher $\Delta$ does not always lead to more computational burdensome.

Figure 5.7: Average time costs of $\operatorname{SM}(d, d)$ for Class 5 .

Figure 5.8: Average time costs of SM-HA for Class 5.

SM-HA proved to be the most eminent model, especially when the number of item types is substantial. When $n$ is above a certain threshold, $m$ will not change a lot as more items will share the same height. Therefore, it shows a more robust
graph than $\operatorname{SM}(d, d)$ shows.
To conclude, all models seem to be affected by the change of $\Delta$, but the impacts were different from each other. Although level packing models offer very compact formulations for small $n$ and $\Delta$, their effectiveness as an exact method was countered when $\Delta$ increased. Also, we find that AF could perform well when $W$ and $H$ are relatively small. In the aspect of pattern-based models, their performances were rather robust than those of level packing models. The strip packing model shows a unique characteristic that favors instances with relatively large $n$. Other stagedpattern models show outstanding effectiveness in solving problems to optimality, which seems to depend on $n$, rather than $\Delta$.

## Chapter 6

## Conclusion

In this thesis, we propose several integer linear programming models based on the previous studies on the 2TDK and the 2D2SP. One of the models, POLY, is the unique polynomial-size model for the 2TDK so far. We also suggest valid inequalities for the well-known level packing model, which not only enhance its LP-relaxation value but also make its structure easier to be analyzed. Then, this study establishes a nontrivial theoretical hierarchy between the modified level packing model and the pattern-based models in the aspect of their LP-relaxation values.

Utilizing these formulations to solve problems to optimality requires some techniques such as branch-and-price and branch-and-cut algorithms. For the modified level packing model, we construct a branch-and-cut algorithm. It checks whether the current solution satisfies all valid inequalities at every node. As pattern-based models have exponentially many width patterns or height patterns, several branch-and-price algorithms are devised.

To illustrate the properties of these models in their real usage, this thesis involves computational experiments of both well-known instances and artificial instances. Generally, a gap between the LP-relaxation values of level packing models and pattern-based models was far less than we had expected theoretically.

We then checked the efficiency of each exact method. For relatively small instances, level packing models outperformed other models. However, in solving larger instances, staged-pattern models proved their effectiveness. Although all patternbased models generally provided almost near-optimal objective values within the time limit, solving instances to optimality was better achieved by staged-pattern models. Tightened upper bounds by height patterns may contribute to this result. In the aspect of demand sensitivity, level packing models had difficulty in solving instances with many duplicated items. The performance of AF and POLY in general was so poor that they may need more elaborate modifications for their real usage.

To conclude, this study extends the options for solving the 2TDK based on analysis in various situations. Theoretically, we develop an arc-flow model, stagedpattern models, and a novel polynomial-size model and prove that the upper bound provided by the staged-pattern model is nearest to the optimal objective value. Computationally, we verify that staged-pattern models implemented with branch-and-price algorithms are eminent.

For future works, the theoretical relationship between AF and ML is still unknown. In addition, as we focus on revealing some unknown properties of proposed models, more elaborate algorithms and heuristics can be devised based on our results. For example, tightening upper bounds in the branch-and-price procedure for patternbased models may improve its performance dramatically. A direct relationship between the obtained upper bound and the objective value or approximation ratios of algorithms may also be established as Steinberg [24] did for the two-dimensional packing problem. Lastly, finding a polynomial-size formulation with a decent quality of upper bounds provided by its LP-relaxation is an intriguing issue.

## 국문초록

본 논문은 2 단계 길로틴 절단(two-staged guillotine cut)을 사용하여 이윤을 최대화하는 2 차원 2 단계 배낭 문제(two-dimensional two-staged knapsack problem: 이하 2TDK) 에 대한 정수최적화 모형과 최적해법을 다룬다. 우선, 본 연구에서는 스트립패킹모형, 단계패턴모형, 레벨패킹모형, 그리고 호-흐름모형과 같은 정수최적화 모형들을 소개한 다. 그 뒤, 각각의 모형의 선형계획완화문제에 대해 상한강도를 이론적으로 분석하여 상한강도 관점에서 모형들 간 위계를 정립한다. 또한, 본 연구에서는 $2 T D K$ 의 다항크기 (polynomial-size) 모형의 존재성을 처음으로 증명한다. 다음으로 본 연구는 $2 T \mathrm{TDK}$ 의 최적해를 구하는 알고리즘으로써 패턴기반모형들에 대한 분지평가 알고리즘과 레벨패 킹모형을 기반으로 한 분지절단 알고리즘을 제안한다. 단계패턴모형이 이론적으로도 가장 좋은 상한강도를 보장할 뿐만 아니라, 계산 분석을 통해 단계패턴모형을 기반으로 한 분지평가 알고리즘이 제한된 시간 내 좋은 품질의 가능해를 찾음을 확인하였다.

주요어: 정수최적화 모형, 2 차원 2 단계 배낭 문제, 분지평가 알고리즘, 분지절단 알고 리즘, 비교분석
