## **Abstract**

# Biological and Mechanical Properties of MAX Phases and MXene/PLA Nanocomposites

Chen Ke

Department of Materials Science and Engineering

Seoul National University

Dental implant surgery has been popularly trusted by the worldwide patients for oral rehabilitation. However, the poor resistance to physical abrasion and fatigue fracture, and the detrimentally released ions of the traditional Ti-based materials (such as pure Ti and Ti-6Al-4V alloy) are crucial factors from the aspect of materials influencing on the survival rates. MAX phase is a terminology for a family of layered ternary compounds, which possess high flexural strength, fracture toughness, and damage tolerance, good tribological properties, excellent machinability, and

good oxidation and corrosion resistance because of their unique structure, in which alternate near-close-packed layers of covalent  $M_6X$  octahedrons are interleaved with metal-like A atom layers. Therefore, MAX phases have the potential to be used in the biomedical application, in particularly dental and orthopedic fields. Nevertheless, the results of previous works which merely focus on the  $Ti_3SiC_2$  are inconsistent. The reason for this phenomenon is still blurry. Since the biological responses to host tissue cells must be considered in the development of synthetic biomaterials, it is essential to systematically evaluate the biocompatibility of MAX phase and establish the general mechanism for such a numerous family (more than 70 members).

This thesis first explored the biocompatibility of the selected MAX phases ( $Ti_3AlC_2$ ,  $Ti_3SiC_2$ , and  $Ti_2AlN$ ) on basis of different A-site and X-site atoms. The results of cell tests showed that these phases were innocuous to preosteoblasts and fibroblasts. Compared with the strong viable fibroblasts, the different cellular responses of these materials were clearly distinguishable for the preosteoblasts. Under an osteoblastic environment,  $Ti_2AlN$  exhibited better cell proliferation and osteogenic differentiation performance than  $Ti_3AlC_2$  and  $Ti_3SiC_2$ . Moreover, the performance was superior to that of a commercial Ti-6Al-4V alloy and comparable

to that of pure Ti. A general mechanism was suggested based on the different surficial oxidation products, which were determined from the binding energy of the adsorbed  $\text{Ca}^{2+}$  ions using first-principles calculations. Compared with the partially oxidized  $\text{TiC}_x\text{O}_y$  layer on  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$ , the partially oxidized  $\text{TiN}_x\text{O}_y$  layer on the  $\text{Ti}_2\text{AlN}$  had a stronger affinity to the  $\text{Ca}^{2+}$  ions, which indicated the good biocompatibility of  $\text{Ti}_2\text{AlN}$ . In addition, the (001) surfaces were proved to possess the strongest binding energy with the  $\text{Ca}^{2+}$  ions in a certain MAX phase. This phenomenon disclosed the good biocompatibility of the 2-dimensional transition metal carbides or nitrides (MXenes), which mainly were composed of these (001) surfaces.

Guided bone regeneration (GBR) technique is a reliable and validated therapy to augment the bone for the surgery of dental implantation. Although the resorbable GBR membrane is fascinating, which protects the bone healing from the interference of non-osteogenic tissue, and exempts the secondary surgery for the removal of remaining membrane, the poor mechanical properties and cellular responses are critical issues, which usually result in insufficient amount of regenerated bone. In the second work of this thesis,  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets (delaminated  $\text{Ti}_3\text{C}_2\text{T}_z$ , d- $\text{Ti}_3\text{C}_2\text{T}_z$ ), the representative of MXenes, were used to

enhance the mechanical properties and biocompatibility of Poly (lactic acid) (PLA) membrane. As a prerequisite, the intrinsic biocompatibility of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was first authenticated using that of widely-discussed graphene oxide (GO) for reference. The strong and biocompatible d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> enhanced PLA nanocomposite membranes were fabricated using the interfacial mediation with n-octyltriethoxysilane (OTES). To the best of our knowledge, this was the first effort to introduce MXene into polymer matrix for biomedical applications. The optimized ultimate tensile strength (UTS) of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membrane was 72 MPa (obtained at 0.5 wt.%), which increased by 33%. This enhancement was almost the highest compared with the graphene-enhanced works, where the solvent casting was adopted. The reason could be ascribed to the strong interaction between OTES-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and PLA, which ensured the efficient load transferring between these two components. The d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was also certified to significantly promote the adhesion, proliferation, and osteogenic differentiation of preosteoblasts on the nanocomposite membranes, which exhibited ascending trend along with the increasing filler content (0 to 1 wt.%).

**Keywords:** Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>2</sub>AlN, Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>, Poly (lactic acid), *In vitro* test,

First-principles calculation, Biocompatibility, Mechanical properties.

# **Chapter 1.**

## **Introduction**

## 1.1 Generalities of Ti-based Materials for Dental Application

According to the statistics of *American Association of Oral and Maxillofacial Surgeons* (AAOMS), 69% of adults whose age are from 35 to 44, have lost at least one permanent tooth because of an accident, gum disease, a failed root canal or natural tooth decay. <sup>[1]</sup> Dental implantation is a popular therapy for effective restoration, which has progressed rather rapidly over the past two decades. The number of patients receiving the dental implant surgery has increased steadily all over the world, reaching about one million dental implantations per year. <sup>[2]</sup> The demand is still booming particularly in China. The annual rate is expected to 30% due to the low implant penetration in contrast with that in Italy and South Korea (*China Industry Research*) (**Fig. 1.1**). Although the dental implantation is a kind of mature technique, the failures happen from time to time (survival rates range is from 90% to 96.5%) <sup>[3,4]</sup> because of the inflammation, implant fractures, physical abrasion, fatigue crack, implant loosening and exposure of implant. <sup>[5,6]</sup> Besides the infection during or after surgery, and undesirable personal conditions of the patients (such as insufficient alveolar bone, and periodontitis), the incomplete mechanical properties and biocompatibility of the materials are also the critical problems.

**Fig. 1.1.** The ratio of implant penetration to tooth restoration. The image is reprinted from *DENTSPLY IMPLANTS magazine*.<sup>[1]</sup>

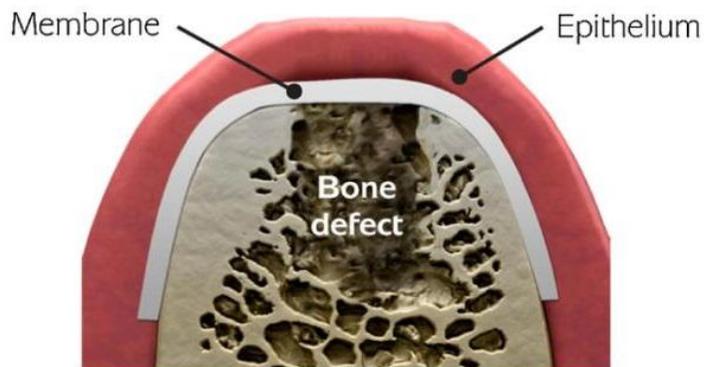

Ti-based materials have good biocompatibility because the partially released Ti ion is very active and rapidly reacts with hydroxyl radicals or anions in body fluid to form the oxides or salts, so that the Ti ion will not combine with the biomolecules, which might interfere the normal physiology. Likewise, the passive layer consisting of compact  $TiO_2$  can prevent the further corrosion.<sup>[7, 8]</sup> Traditional Ti-based materials such as pure Ti (ASTM grade 4) and Ti-6Al-4V (ASTM grade 5) have been proverbially used as the bone substitutes, dental implant, screw fixation and many other orthopedic applications because of their good biocompatibility and high mechanical properties.<sup>[9-13]</sup> However, the physical abrasion resistance and fatigue fracture of pure Ti and Ti-6Al-4V alloy need to be enhanced regarding as the dental

materials. <sup>[13-15]</sup> The native formed TiO<sub>2</sub> film is easily fractured because of the poor mechanical properties under the conditions of fretting and sliding wear. <sup>[16]</sup> Hence, more V ions will be released from the Ti-6Al-4V alloy before the regeneration of TiO<sub>2</sub> film. These detrimental ions probably result in gastrointestinal discomfort, and even have a toxic effect on the liver and kidney, <sup>[17, 18]</sup> which is supposed to be avoided in the biomedical applications. <sup>[19, 20]</sup>

Nowadays, titanium carbide (TiC), titanium nitride (TiN), titanium oxy nitride (TiON) and titanium aluminum nitride (TiAlN) have been widely used as the coating film to strengthen the surficial hardness and wear resistance of the pure Ti and Ti-6Al-4V alloy, which is also helpful to reduce the releasing of V ions. <sup>[14, 21, 22]</sup> However, the interface between the coating and substrate is always a weak defect. The preparation process of corresponding bulks mainly consisting of these brittle refractory titanium carbide or nitride needs quite high sintering temperature (more than 2000 K). <sup>[23]</sup> Therefore, the development of new Ti-based materials with better mechanical properties and biological responses is always the intriguing trend for dental materials. <sup>[5]</sup>

## 1.2 Generalities of Guided Bone Regeneration (GBR) Membrane

Guided bone regeneration (GBR) is a reliable and validated therapy which has been widely used in oral rehabilitation with the placement of dental implants and periodontal regeneration. <sup>[24-26]</sup> The basic concept of GBR strategy is based on the hypothesis that protecting the bone healing of the defect from the interference of non-osteogenic tissue (such as epithelial tissue) using a GBR membrane <sup>[25-27]</sup> (**Fig. 1.2**). This membrane should maintain the space of the osseous defect, exclude the soft tissue cells, as well as possess good biological affinity, tissue integration, and ease of use. <sup>[27, 28]</sup>

**Fig. 1.2.** Schematic illustration of GBR membrane used in augmenting the bone for dental implant. (The figure is reprinted from *Dental Materials*) <sup>[26]</sup>

The GBR membrane can be roughly classified to two generations. Compared with non-resorbable Ti and expanded polytetrafluoroethylene (ePTFE) membranes, the resorbable membranes, such as poly (lactic acid) (PLA), poly (glycolic acid) (PGA), poly ( $\epsilon$ -caprolactone) (PCL) and their copolymers or tissue-derived collagens, chitosan, gelatin, and silk fibroin, are more fascinating because of the exemption from the secondary surgery to extract the remaining membrane. [26, 29]

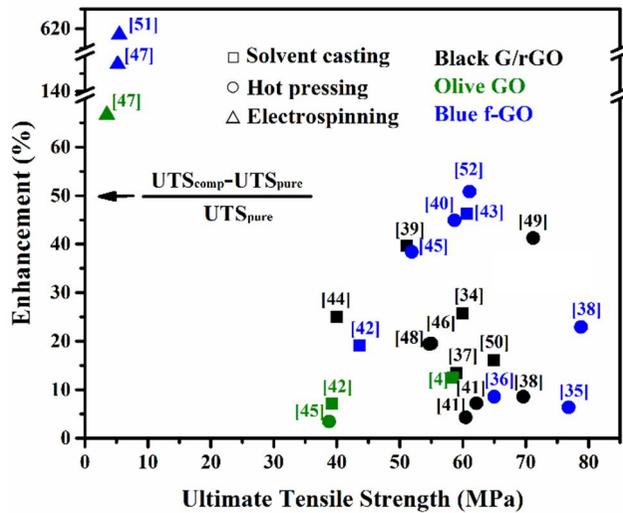

Nowadays, the commercial GBR membranes are mainly fabricated using the above materials. For instance, the representatives of non-resorbable membranes: Gore-Tex<sup>®</sup> (e-PTFE), High-density Gore-Tex<sup>®</sup> (high-density PTFE), and Gore-Tex-Ti<sup>®</sup> (Ti reinforced PTFE); the representatives of resorbable membranes: Guidor<sup>®</sup>, Epi-Guide<sup>®</sup>, and Vivosorb<sup>®</sup> are mainly made of PLA; Resolut Adapt<sup>®</sup> and Biomesh-S<sup>®</sup> are mainly made of PLGA; And Bio-Gide<sup>®</sup>, Ossix<sup>®</sup>, Biomend<sup>®</sup>, Dentium<sup>®</sup>, Lyoplant<sup>®</sup>, Cytoplast<sup>®</sup>, and Heal-All<sup>®</sup> are mainly made of collagen. [28]

Notwithstanding the good biocompatibility of naturally derived polymers, the synthetic polymers are more handily to control the biodegradability, rigidity, manageability, processability, and drug-encapsulating ability. Likewise, they have more convenient and stable source of the raw materials, which can avoid the possible disease transmission from the animals. [30-33] However, the poor mechanical

properties <sup>[29]</sup> and cell affinity <sup>[26, 29]</sup> are crucial issues for these resorbable membranes, which result in insufficient amount of regenerated bone. For instance, David Schneider and his cooperators compared the clinical performances between titanium-reinforced expanded polytetrafluorethylene membrane and modified polylactide-co-polyglycolide acid membrane. The results showed that in the cases of resorbable membrane, the horizontal thickness of regenerated bone was much thinner than in the cases of the PTFE membrane. Meanwhile, the membrane exposure happened more frequently in the cases of the resorbable membranes. <sup>[29]</sup>

The incorporation of secondary phase is one of the effective methods to enhance the polymer matrix. Currently, graphene and its derivatives have been corroborated to strengthen the mechanical properties of polymeric matrices (classified in **Fig. 1.3**) Herein, the PLA is selected as the matrix for summary owing to its wide application in commercial GBR membrane. <sup>[34, 35, 43]</sup> The graphene (G) or reduced graphene oxide (rGO) which has relatively hydrophobic surface is more efficacious than the hydrophilic bare GO. Whereas, the GO can be also used to reinforce the mechanical properties of hydrophobic PLA effectively after the modification of interface. In addition, these nanosheets are also discovered to promote interfacial bio-interactions including: **(1)** Adsorbing and concentrating

nutrition factors; **(2)** Mediating their cellular signaling and biological performance with co-cultured cells; **(3)** Accelerating cell adhesion and growth, and affecting cell proliferation and differentiation. <sup>[53-55]</sup>

**Fig. 1.3.** Classification of the ultimate tensile strength (UTS) and its enhancement of PLA nanocomposite which was enhanced by graphene (G) or reduced graphene graphene (rGO), GO, and functional group modified GO (f-GO) from the previous references. <sup>[34-52]</sup>

### 1.3 Generalities of MAX Phases

The layered ternary machinable ceramics,  $M_{n+1}AX_n$  phases, are composed of an early transition metal (**M**), an A-group element (**A**), and a C and/or N (**X**); and  $n$  equals to 1-6 (**Fig. 1.4**).<sup>[56, 57]</sup> MAX phases exhibit good tribological properties, damage tolerance, and oxidation and corrosion resistance because of their unique structure, in which alternate near-close-packed layers of covalent  $M_6X$  octahedrons are interleaved with metal-like A atom layers.<sup>[56, 58-63]</sup> For instance, the commonly discussed Ti-based MAX phases,  $Ti_3AlC_2$ ,  $Ti_3SiC_2$ , and  $Ti_2AlN$ , have much greater flexural strength and fracture toughness (such as  $Ti_3AlC_2$ , 340–450 MPa<sup>[64]</sup> and 4.6–9.1 MPa·m<sup>1/2</sup><sup>[63]</sup>;  $Ti_3SiC_2$ , 720 MPa<sup>[65]</sup> and 4.5–16 MPa·m<sup>1/2</sup><sup>[63]</sup>;  $Ti_2AlN$ , 350–371 MPa<sup>[66]</sup> and 8.2 MPa·m<sup>1/2</sup><sup>[67]</sup>) than those of common bioceramics (such as hydroxyapatite, 65–85 MPa<sup>[68]</sup> and 0.65–0.70 MPa·m<sup>1/2</sup><sup>[69]</sup>). Therefore, these machinable ceramics have been used as the concrete dry drills, gas burner nozzles, heat exchangers and screw.<sup>[56, 63]</sup>

**Fig. 1.4.** The elements composition of  $M_{n+1}AX_n$  phases.

In the previous researches, the MAX phase ( $Ti_3SiC_2$ ) has been discussed as the structural materials in biomedical application because of their attractive mechanical properties. [70-72] Gao and Miyamoto et al [71] deemed that the  $Ti_3SiC_2$  (3 vol. % TiC) was bio-inert. After 24-week implantation in tibia periosteum of rabbit, there was no adverse foreign body reaction being observed. In addition, the  $Ti_3SiC_2$  exhibited a good performance to resist the corrosion of 0.9 wt. % NaCl solution. However, Ngai et al [72] found that when the SiC-reinforced  $Ti_3SiC_2$  composite was implanted into the femur of New Zealand rabbit, a few of foreign-body granulomas and eosinophilic leukocytes could be observed after 10-week implantation; However, the surface of composite maintained intact as before. Owing to the lack of control

group such as pure  $\text{Ti}_3\text{SiC}_2$  or SiC in their experiment, it was difficult to exactly evaluate the biocompatibility of these  $\text{Ti}_3\text{SiC}_2$ -based composites. For the specific applications, Shi et al and cooperators [73, 74] utilized the  $\text{Ti}_3\text{SiC}_2$  powders as the secondary phase to strengthen and toughen the hydroxyapatite. The bending strength and fracture toughness of the composite were confirmed to increase from 75 to 250 MPa, and from 0.8 to 3.9  $\text{MPa}\cdot\text{m}^{1/2}$ , along with the decreasing of Vickers hardness. This composite even performed excellent machinability when the loaded content of  $\text{Ti}_3\text{SiC}_2$  was more than 20 vol. %.

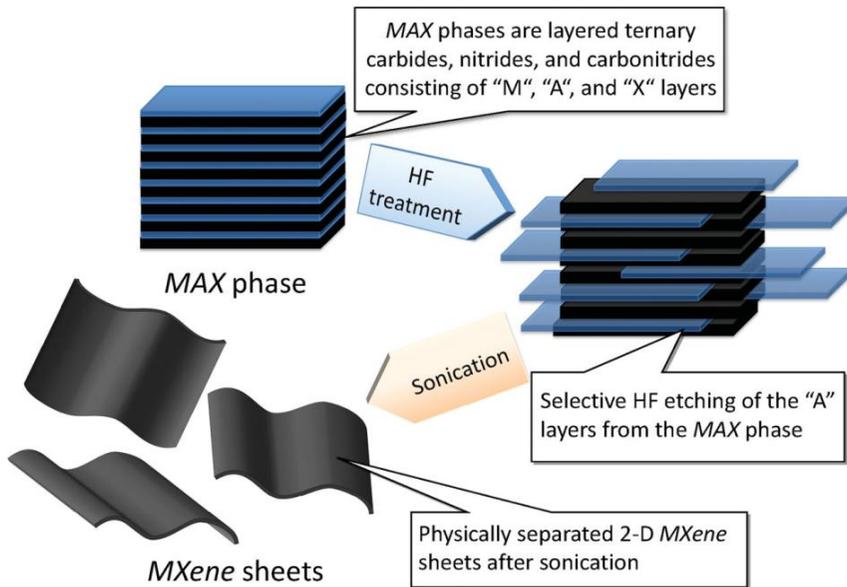

Nevertheless, all the above current researches concentrate on the  $\text{Ti}_3\text{SiC}_2$ . The reasons for inconsistent biological behaviors remains unclear, and verification of the biocompatibility of MAX phases, especially for the other phases in this large family (more than 70 members), remains insufficient. It is important and necessary to establish the general mechanism on the biocompatibility of MAX phases for doping out the potential application of the overall phases in biomedical fields.

## 1.4 Generalities of 2D Metal Carbides or Nitrides (MXenes)

Recently, the burgeoning two-dimensional (2D) materials such as graphene, transition metal dichalcogenides (TMDs), boron nitrides, and MXenes possessing distinctive properties from their three-dimensional (3D) counterparts have attracted tremendous attention. [75-79] MXenes is an emerging family of 2D early transition metal carbides or nitrides, derived by the selective exfoliation of “A” layers with chemical etching from MAX phases (such as hydrofluoric acid, ammonium hydrogen difluoride or lithium fluoride-hydrochloric acid mixture solution), and following physical delamination with sonication (**Fig. 1.5**). [56, 62, 79-81] Therefore, there are two kinds of typical morphologies of MXene. The accordion-like stacked MXene (exfoliated MXene, e-MXene) is obtained after the chemical exfoliation. The MXene nanosheet (delaminated MXene, d-MXene) is obtained after the delamination of e-MXene using the sonication with the intercalated molecules such as dimethyl sulfoxide (DMSO), H<sub>2</sub>O and Li<sup>+</sup> ion. To date, quite a vast number of MXenes have been synthesized with the general formula of M<sub>n+1</sub>X<sub>n</sub>T<sub>z</sub> (where M is an early transition metal, X is a C and/or N, n is 1, 2, 3, and T<sub>z</sub> stands for the terminated groups, such as -OH, -O and -F). [79, 80, 82, 83] (**Table 1.1**) Owing to the abundance of MAX phases, the composition and structure of MXene are far more

easily to be tunable than that of graphene. For instance, the porous MXene (porous  $\text{Ti}_3\text{C}_2\text{T}_z$ ,  $\text{V}_2\text{CT}_z$ , and  $\text{Nb}_2\text{CT}_z$ ) can be fabricated using the oxidation and following acid etching of the specific metal ions. <sup>[84]</sup> In addition, the sandwich-like ordered double transition metal MXene,  $\text{Mo}_2\text{TiC}_2\text{T}_z$ ,  $\text{Mo}_2\text{Ti}_2\text{C}_3\text{T}_z$ , and  $\text{Cr}_2\text{TiC}_2\text{T}_z$ , can be obtained using the adjustment of M-site atom. <sup>[85]</sup> Moreover, MXene can be composed of nitrides, such as the  $\text{Ti}_4\text{C}_3\text{T}_z$ , which is obtained from the etching of molten fluoride salt (LiF, NaF, and KF at 550 °C) from the  $\text{Ti}_4\text{AlN}_3$ . <sup>[86]</sup> As special cases, the  $\text{Zr}_3\text{C}_5\text{T}_z$ ,  $\text{Hf}_3\text{C}_2\text{T}_z$ ,  $\text{SCT}_z$ , and  $\text{Mo}_2\text{CT}_z$  nanosheets can be synthesized using the etching of  $\text{Al}_3\text{C}_3$  from  $\text{Zr}_3\text{Al}_3\text{C}_5$ , the etching of Ti from  $\text{Ti}_2\text{SC}$ , and the etching of Ga from  $\text{Mo}_2\text{Ga}_2\text{C}$ , separately. <sup>[87-90]</sup>

These nanosheets possess large specific surface area, excellent electrical conductivity, and good hydrophilicity, which grant them desirable candidates for versatile applications such as in energy storage (such as the electrode for supercapacitor, lithium-ion battery, and lithium–sulfur battery), <sup>[91-93]</sup> surface absorbent (such as Pb(II), Cr(VI), and U(VI)), <sup>[94-96]</sup> and sensor device (such as temperature,  $\text{CO}_2$ , nitrite, and  $\text{H}_2\text{O}_2$ ). <sup>[97-100]</sup>

**Fig. 1.5.** Schematic diagram describing the synthesis process of MXenes from MAX phases. The image is reprinted from *ACS Nano*.<sup>[80]</sup>

	Mo <sub>2</sub> Ga <sub>2</sub> C	Mo <sub>2</sub> CT <sub>z</sub> [90]

Very recently, MXenes have aroused great interests in the biomedical applications fields. The TiO<sub>2</sub> nanoparticle modified accordion-like Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> (e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>) is confirmed to be used as supporting materials for hemoglobin to detect the concentration of H<sub>2</sub>O<sub>2</sub> (**Fig. 1.6(A)**). This biosensor has high sensitivity (447.3  $\mu\text{A mM}^{-1} \text{cm}^{-2}$ ), wide detection range (0.1–380  $\mu\text{M}$ ), and low detection limit (14

nM).<sup>[98]</sup>  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets ( $\text{d-Ti}_3\text{C}_2\text{T}_z$ ) also exhibits a high antibacterial efficiency with growth inhibition of 99% for Escherichia coli (E. coli) and Bacillus subtilis (B. subtilis), which reveals that MXenes can serve as novel antimicrobial nanomaterials in environmental and biomedical applications (**Fig. 1.6(B)**).<sup>[101, 102]</sup> In addition,  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets ( $\text{d-Ti}_3\text{C}_2\text{T}_z$ ) is discovered to have high efficiency for photothermal conversion and *in vitro/in vivo* photothermal ablation of tumor, which indicates the great potential for cancer therapy (**Fig. 1.6(C)**).<sup>[103]</sup> In particular, the *in situ*-grown  $\text{MnOx/d-Ti}_3\text{C}_2$  composite can be developed as multifunctional theragnostic agents for efficient magnetic resonance (MR) and photoacoustic (PA) dual-modality imaging-guided photothermal therapy (PTT) to oppose the cancer. This charming therapy has efficient tumor detection, high photothermal-conversion performance, and good biocompatibility.<sup>[104]</sup> Similarly,  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets ( $\text{d-Ti}_3\text{C}_2\text{T}_z$ ) can be also trimmed to quantum dots like the graphene quantum dots using hydrothermal method. These MXene quantum dots are photoluminescent (quantum yields up to  $\approx 10\%$ ), which can be used as cellular imaging for macrophage (RAW264.7) (**Fig. 1.6(D)**).<sup>[105]</sup> Finally, the  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets ( $\text{d-Ti}_3\text{C}_2\text{T}_z$ ) can be used to assemble the ultrathin MXene-based field-effect

transistors, which enabled the real-time, label-free monitoring of neuronal spiking activities <sup>[106]</sup>.

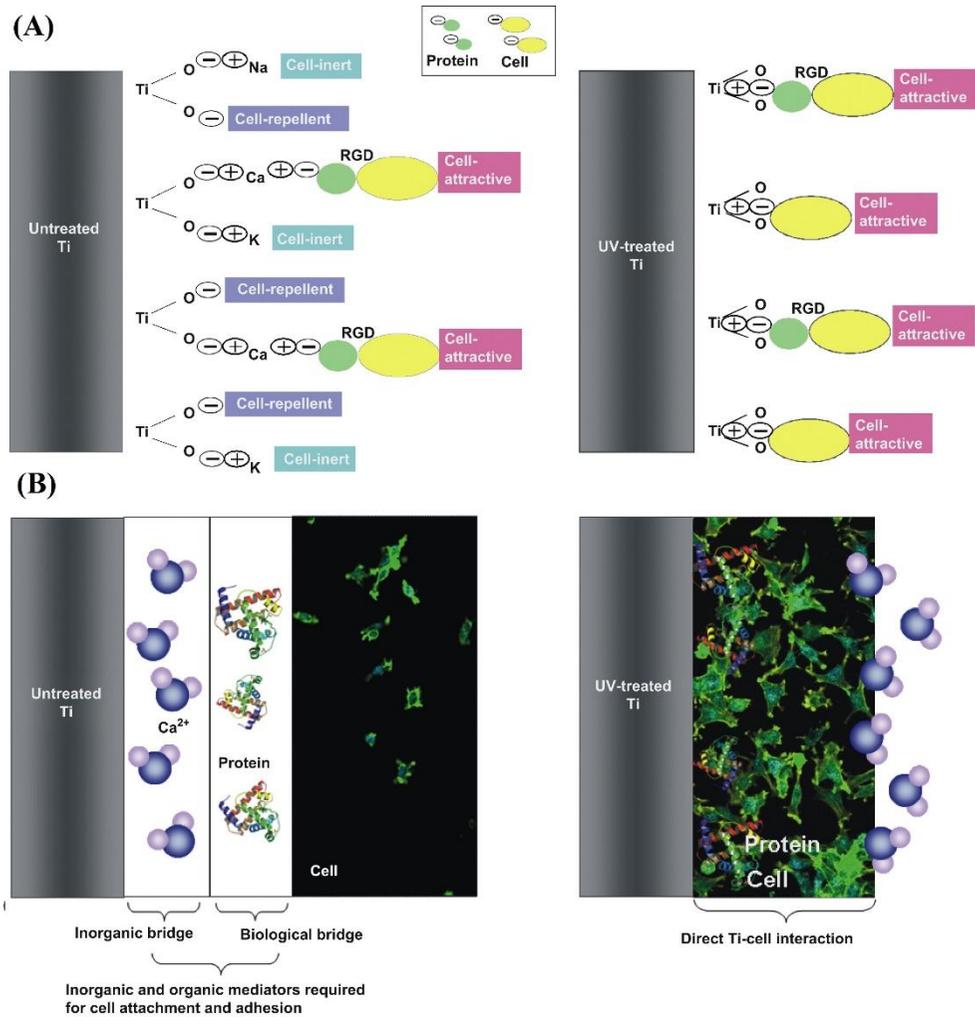

**Fig. 1.6.** Representative applications of MXene ( $\text{Ti}_3\text{C}_2\text{T}_z$ ) in biomedical fields: **(A)** Biosensor, reprinted from *Biosensors and Bioelectronics*; <sup>[98]</sup> **(B)** Antibacterial activity, reprinted from *ACS Nano*; <sup>[101]</sup> **(C)** Photothermal ablation, reprinted from *Nano Letter*; <sup>[103]</sup> **(D)** Cellular imaging, reprinted from *Advanced Materials*. <sup>[105]</sup>

## 1.5 Generalities of Biocompatibility

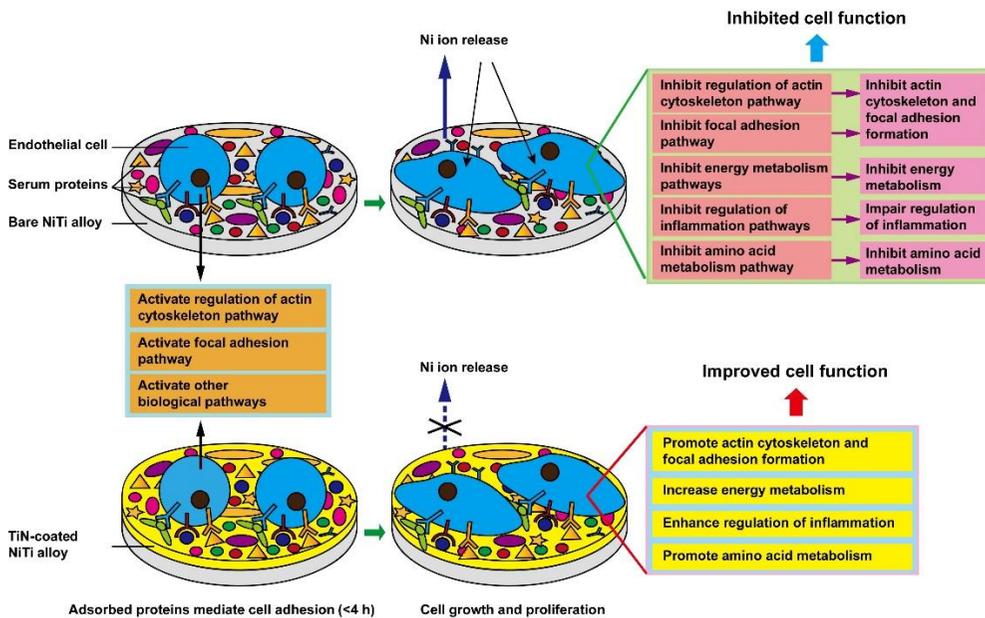

Biocompatibility has been defined as “the ability of a material to perform with an appropriate host response in a specific application”.<sup>[8]</sup> This means that the biomaterials or any leachable products from them do not cause serious cell death, chronic inflammation or other impairment of cellular or tissue functions.<sup>[8]</sup> In addition, the desirables for the biocompatibility should contain non-inflammatory, non-toxic, noncarcinogenic, nonpyrogenic, blood compatible, and non-allergic performances as well.<sup>[107]</sup> To investigate the biocompatibility of biomedical implants, the mechanisms how cells recognize and interact with the extracellular matrix (ECM) influenced by the biomaterials should be first explored.<sup>[108]</sup> There are abundant analytical methods to assess the cellular responses using quantitative or qualitative analyses including cell adhesion, proliferation, migration, differentiation and cell survival.<sup>[108]</sup>

The cell affinity of the biomaterials is known to be affected by the surface hydrophilicity, net charge, topography, chemical composition, and other biochemical-physical properties.<sup>[108, 109]</sup> For instance, the hydrophilic materials

induce a high level of the adhesion and spreading of the MC3T3-E1 cells. <sup>[110]</sup> Meanwhile, the negatively charged surface of the pure Ti can be converted to electropositive charge. <sup>[111]</sup> Ogawa and coworkers found after the treatment of UV-photofunctionalization, the titanium surface was full of cell-attracting terminals consisting of the RGD sequence of proteins or positively charged TiO<sub>2</sub> surface, which served as direct chemoattractants to cells without divalent cations such as Ca<sup>2+</sup> ions (**Fig. 1.7**). <sup>[111]</sup> There is also a consensus that roughening the implant surface at microscale and even at nanoscale can lead to a stronger bony response. <sup>[112]</sup> In addition, these above factors usually interact each other. The hydrophilicity of biomaterials is easily to be tailored by the surface topography and net charge. Furthermore, the investigation of biomolecular mechanism is essential and important for the biological effects between the implant and cells. For instance, the TiN coating on the NiTi alloy not only effectively prevented the release of Ni ions, but also promoted the formation of actin cytoskeleton and focal adhesion, increased energy metabolism, enhanced regulation of inflammation, and promoted amino acid metabolism, thus improved the cell functions (**Fig. 1.8**). <sup>[113]</sup>

**Fig. 1.7.** Schematic description of the mechanism of electrostatic interactions underlying the UV-photofunctionalization of titanium dioxide surfaces: UV-mediated conversion of titanium surfaces from bioinert to bioactive. **(A)** Electrostatic interaction of TiO<sub>2</sub> surfaces with ions, proteins and cells. **(B)** A distinct interfacial layer formation at UV-photofunctionalized titanium surfaces. The image is reprinted from *Biomaterials*.<sup>[111]</sup>

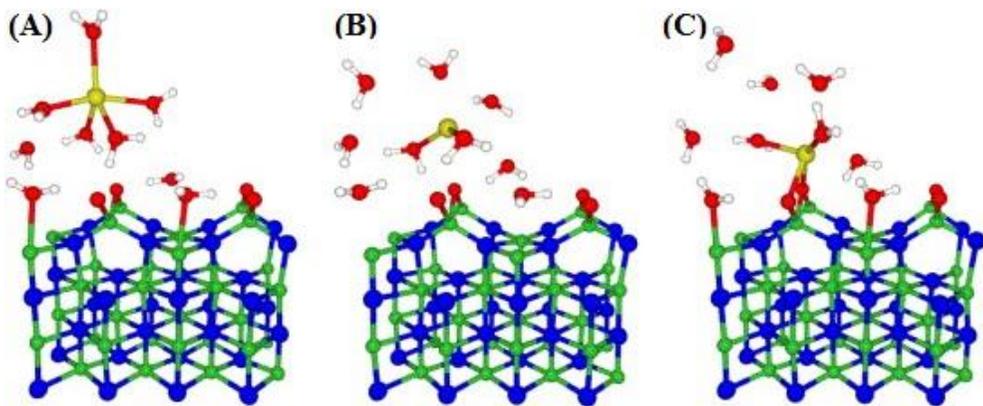

**Fig. 1.8.** Schematic diagram of mechanism for different effects of bare and TiN-coated NiTi alloys on endothelial cell function. The image is reprinted from *Biomaterials*.<sup>[113]</sup>

In theoretical simulations, the adsorption process of  $\text{Ca}^{2+}$  ions on the surface of the biomaterial is widely used as the representative marker especially for bony tissue,<sup>[114, 115]</sup> since the  $\text{Ca}^{2+}$  ion plays a prominent role bridging a net negatively charged substrate and anionic protein (integrin) for cell attachment.<sup>[111]</sup> Likewise, the deposition of calcium is the first step for the nucleation of the calcium phosphate, which is critical for the implants in contact with the bony tissue.<sup>[114, 115]</sup>

Stefano and coworkers demonstrated that the  $\text{TiN}_x\text{O}_y$  surface could initiate the

spontaneous nucleation of calcium phosphate because of the presence of a high electronegatively charged surface, which was about  $-0.80$  (**Fig. 1.9**).<sup>[114]</sup> This phenomenon was also discovered on the surface of  $\text{TiO}_2$ , where the lowest electronegative charge of (011) surface was  $-0.45$ .<sup>[115]</sup>

**Fig. 1.9.** Snapshots from a FPMD simulation at 300 K showing the adsorption of a  $\text{Ca}^{2+}$  ion on the hydrated partially oxidized TiN surface. (A) Initial configuration, after relaxation of the system for  $\sim 300$  fs keeping fixed the  $\text{Ca}^{2+}$  ion; (B) After  $\sim 180$  fs of simulated time; (C) After  $\sim 650$  fs of simulated time. The image is reprinted from *Acta Materialia*.<sup>[114]</sup>

## 1.6 Purpose and Meaning of the Project

The biological responses to host tissue cells must be considered in the development of synthetic biomaterials. <sup>[108]</sup> In this thesis, the biocompatibility of selected MAX phases ( $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$ ) will be systematically investigated using cell adhesion, proliferation, and differentiation with preosteoblasts and fibroblasts. Moreover, first-principles calculations will be employed to further reveal the general mechanism. The aim of the first part of this thesis is to explore the factors that affect the biocompatibility of MAX phases from the direction of different chemical compositions and to establish a reasonable mechanism to speculate the biocompatibility of other MAX phases. Then, the second part focuses on a practical dental application of  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets. The  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets will be embedded into PLA for exploring the potential application as a GBR membrane. To the best of our knowledge, this is the first effort to introduce MXene to polymer matrix for biomedical application. The uniaxial tensile test and *in vitro* tests will be employed to confirm whether  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets can enhance the mechanical properties and biocompatibility of PLA membrane.

## **Chapter 2.**

# **Biocompatibility of Selected MAX Phases ( $\text{Ti}_3\text{AlC}_2$ , $\text{Ti}_3\text{SiC}_2$ , and $\text{Ti}_2\text{AlN}$ ): *In Vitro* Tests and First-Principles Calculations**

## 2.1 Introduction

In the previous references, the MAX phase has been introduced to the biomedical fields as a structural material or secondary phase to strengthen and toughen hydroxyapatite. <sup>[70-74]</sup> However, the previous works merely concentrate on the  $\text{Ti}_3\text{SiC}_2$ , and the reason for the inconsistent results remains indistinct. Since the biological responses to host tissue cells must be considered in the development of synthetic biomaterials, <sup>[108]</sup> it is essential to systematically evaluate the biocompatibility of MAX phase and establish the general mechanism for such a numerous family (more than 70 members).

In this chapter, the biocompatibility of selected MAX phases ( $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$ ) will be systematically investigated using cell adhesion, proliferation, and differentiation with preosteoblasts and fibroblasts. Moreover, the first-principles calculations will be employed to further reveal the mechanism. The aim of this chapter is to explore the factors that affect the biocompatibility of MAX phases from the direction of different chemical compositions and to establish a reasonable mechanism to speculate the biocompatibility of other MAX phases.

## **2.2 Preparation and Characterization of Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, and Ti<sub>2</sub>AlN Bulks**

### **2.2.1 Preparation of Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, and Ti<sub>2</sub>AlN Bulks**

The Ti<sub>3</sub>AlC<sub>2</sub> and Ti<sub>3</sub>SiC<sub>2</sub> bulks were prepared from the commercial powders (98%, 300 mesh, Beijing Jinhezhi Materials Co., Ltd., China) using hot pressing sintering (ZT-60-24Y, Chenhua Co., Ltd., China) in an Ar atmosphere with a maximum pressure of 20 MPa. The heating rate was 10 °C/min, and the temperature was held for 2 h at 1350 °C for Ti<sub>3</sub>AlC<sub>2</sub>, and at 1400 °C for Ti<sub>3</sub>SiC<sub>2</sub>. The Ti<sub>2</sub>AlN bulks were synthesized *in-situ* using a pulse-electric-current-aided sintering device (HP D 25/3; FCT Group, Germany) with a Ti–1.1Al–TiN ground powder mixture (Ti and Al, 99.5%, 300 mesh; TiN, 300 mesh, 99.9%; Targets Research Center of General Research Institute for Nonferrous Metals, China) in an Ar atmosphere. The green pellet was then calcined in a graphite mold at 1350°C for 1 h with a maximum pressure of 30 MPa. <sup>[116]</sup>

All the specimens were processed into 10 mm × 10 mm slices (for cell adhesion and proliferation) and 20 mm × 20 mm slices (for cell differentiation)

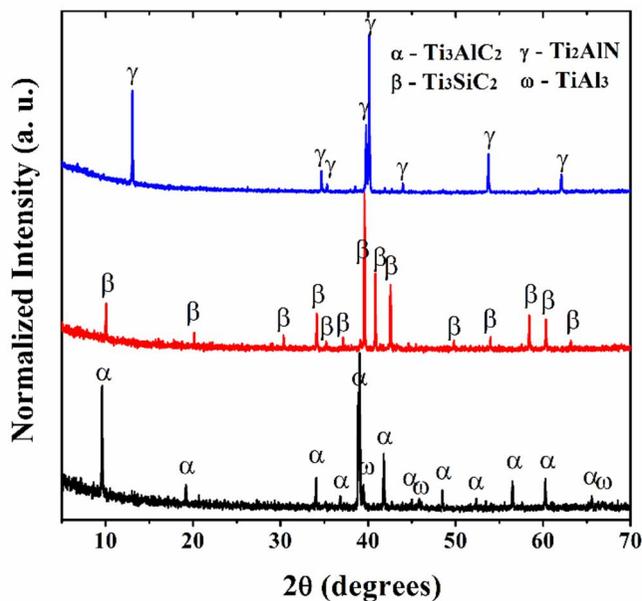

using wire cut electric discharge machining. Before the *in vitro* tests, the slices were sequentially polished using 400, 800, and 1500 grit SiC paper. Then, the as-rinsed slices were disinfected in ethanol for 30 min and ultraviolet rays for at least 3 days in a clean bench.

## **2.2.2 Characterization of $Ti_3AlC_2$ , $Ti_3SiC_2$ , and $Ti_2AlN$ Bulks**

### **2.2.2.1 Characterization Methods**

The chemical phase-analysis of the synthesized MAX phases were evaluated using X-ray Diffraction (XRD, Bruker AXS D8 Advance, Germany) with Cu  $K_{\alpha}$  radiation and their spectra were collected at a step scan of  $0.02^{\circ} 2\theta$  and a step time of 0.2 s. The microstructure was observed using field emission scanning electron microscope (SEM, Merlin Compact, ZEISS, Germany) equipped with energy dispersive spectroscopy (EDS, Thermo Scientific, USA). The surficial composition was detected using X-ray photoelectron spectroscopy (XPS, AXIS-His, Kratos, Japan). The hydrophilicity was evaluated based on the contact angle with approximately 10  $\mu$ L of deionized water using a goniometer (Phoenix 300, Korea) at ambient atmosphere.

### 2.2.2.2 Discussion

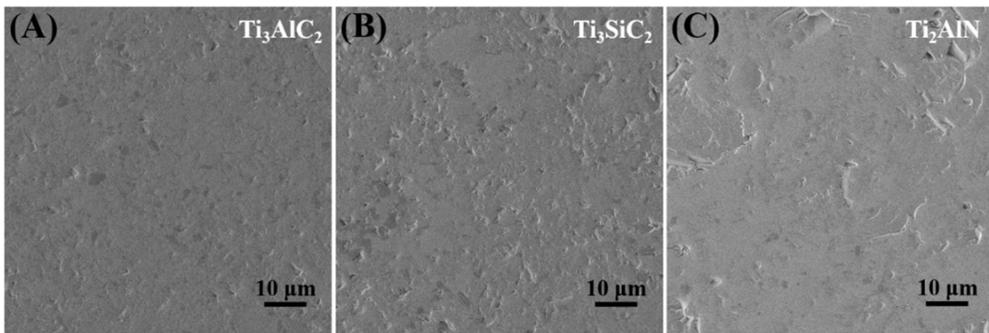

**Fig. 2.1.** XRD spectra of the self-prepared Ti<sub>3</sub>AlC<sub>2</sub> (black line), Ti<sub>3</sub>SiC<sub>2</sub> (red line), and Ti<sub>2</sub>AlN (blue line) bulks.

The phase composition of each self-made MAX phase bulk was determined using XRD. The spectra in **Fig. 2.1** indicated that all the MAX phase bulks possessed a high purity. In particular, for Ti<sub>3</sub>SiC<sub>2</sub> and Ti<sub>2</sub>AlN bulks, no apparent impurity peaks were observed. For the Ti<sub>3</sub>AlC<sub>2</sub> bulk, the amount of remaining intermetallic TiAl<sub>3</sub> was approximately 2 wt. % according to the supplier. However,

this intermetallic phase commonly exists in Ti-6Al-4V alloy, <sup>[117, 118]</sup> which is proverbially used as a commercial biomaterial. To the best of our knowledge, the related works did not note that TiAl<sub>3</sub> is harmful to the human body. Hence, we believe that these self-prepared bulks could be used as platforms to evaluate the biocompatibility of the corresponding MAX phases.

The SEM images showed that these platforms used for *in vitro* tests had dense body and similar morphology after being polished by the same 1500 grit SiC paper (**Fig. 2.2A-C**), which meant that during the following analysis of the biocompatibility of MAX phases, the influence from the morphology could be ignored. Moreover, the XPS spectra exhibited that besides the Ti-C bond or Ti-N bond belonged to the MAX phases (i.e. M-X bond), the Ti-O bond and Al-O bond existed on the surfaces of the Ti<sub>3</sub>AlC<sub>2</sub> and Ti<sub>2</sub>AlN, and the Ti-O bond and Si-O bond existed on that of Ti<sub>3</sub>SiC<sub>2</sub>, respectively (**Fig. 2.3-2.5**). The presence of oxygen on the surfaces of MAX phases was also detected by the analysis of EDS (**Table 2.1**). These results were consistent with the previous works, <sup>[119, 120]</sup> which attested that the MAX phases were covered by the partially oxidized layer. This partially oxidized layer was also discovered and demonstrated on the surfaces of TiC and TiN by the experiments and simulations. <sup>[114, 121]</sup>

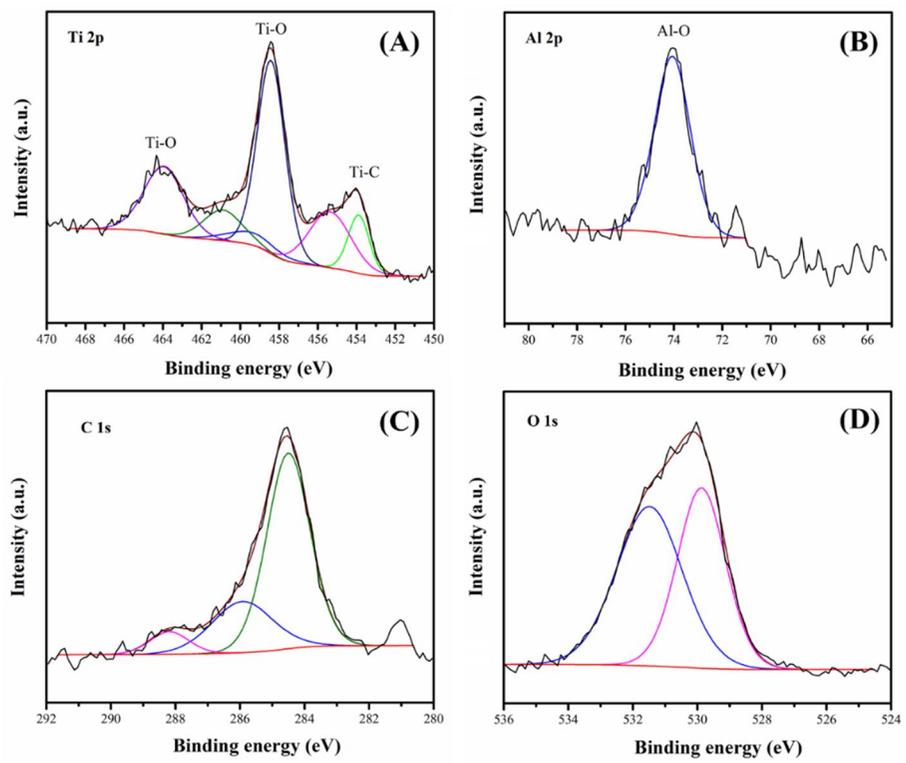

The contact angle test with deionized water showed that the surface of  $Ti_2AlN$  bulk ( $37.0^\circ$ ) was more hydrophilic than those of  $Ti_3AlC_2$  bulk ( $44.4^\circ$ ) and  $Ti_3SiC_2$  bulk ( $45.5^\circ$ ). Meanwhile, the contact angle of  $Ti_2AlN$  bulk ( $37.0^\circ$ ) was also significantly lower than those of the commercial Ti–6Al–4V alloy ( $52.9^\circ$ ) and pure Ti ( $51.6^\circ$ ) as shown in **Fig. 2.6**.

## **2.3 Biocompatibility of MAX Phases: *In Vitro* Tests**

### **2.3.1 Biological Behaviors of Preosteoblasts on the MAX Phases**

#### **2.3.1.1 *In Vitro* Tests Methods**

Since the bony tissue is the main service condition during the dental implantation surgery, a mouse preosteoblast cell line (MC3T3-E1; ATCC, CRL-2593, USA) was first employed in the *in vitro* tests. All the cells were cultivated in alpha-minimum essential medium ( $\alpha$ -MEM, Welgene Co., Ltd., Korea) with fetal bovine serum (FBS; Cellgro, USA) (10% FBS for preosteoblasts) and 1% penicillin streptomycin (Pen Strep; Life Technologies Co., Ltd., USA) in a humidified incubator (Sanyo Co., Ltd., Japan) with 5% CO<sub>2</sub> at 37 °C. A dye-exclusion assay (Trypan blue) was used to count the cells.

The cell adhesion was determined based on the preosteoblasts (1 mL,  $1 \times 10^4$  cells/mL) after being cultured on the surface of the Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, Ti<sub>2</sub>AlN, Ti-6Al-4V alloy and pure Ti bulks for 3 h. The cells were then stained using phalloidin (Life Technology Co., Ltd., USA) and 4', 6-diamidino-2-phenylindole (DAPI, Life Technology Co., Ltd., USA). The morphology and distribution were recorded using the confocal laser scanning microscopy (CLSM; FluoView FV1000, Olympus Co.,

Ltd., Japan). The spreading area of the preosteoblasts was calculated using *ImageTool 3.0* from 50 CLSM images for each material at  $\times 20$  magnification.

The MTS (3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium) assay was used to evaluate the cell proliferation. After being cultured for 3, 5 or 7 days, the optical density (OD) of the formazan product was detected using a microplate reader (EZ Read 400, Biochrom Ltd. UK) at 490 nm. The CLSM was also used to examine the amount and distributions of the preosteoblasts after incubation for 7 days for verification.

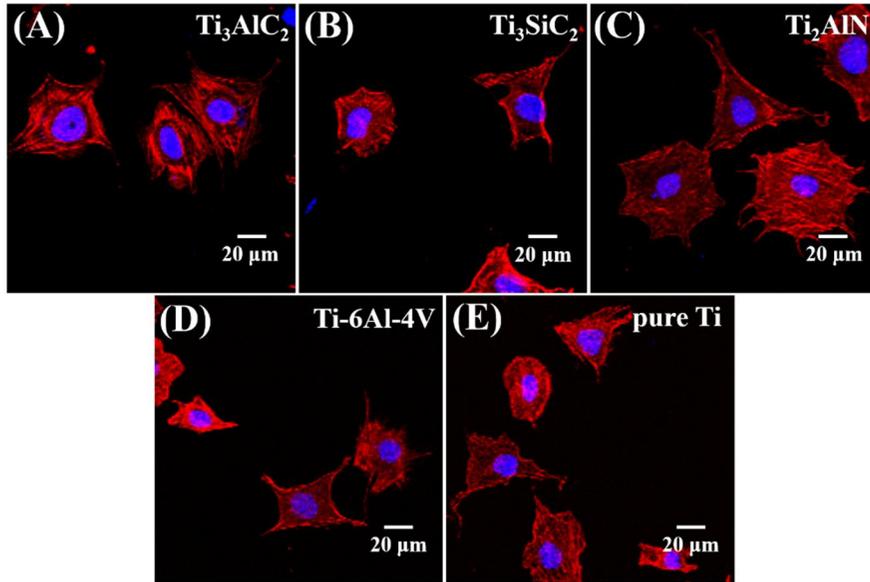

The alkaline phosphatase (ALP) assay was applied to determine the osteogenic differentiation. After incubation for 12 days, the total protein of the cells was determined using the Bio-Rad protein assay kit (Bio-Rad Co., Ltd., USA) based on a series of bovine serum albumin (BSA; Sigma) standards. Then, the ALP activity was predicted based on the color change from p-nitrophenyl phosphate (pNPP, Sigma) to p-nitrophenol (pNP). The amount of ALP was calculated based on the absorbance value at 405 nm (OD value) per milligram of total cellular protein.

All the experiments were conducted with at least three parallel samples. The results are expressed as the mean  $\pm$  standard deviation. A value of  $p < 0.05$  was

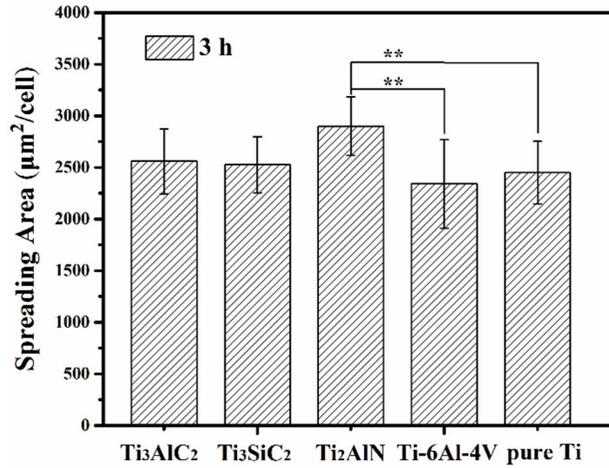

considered statistically significant according to the Student's t-test method using *Statistical Product and Service Solutions* software.

### 2.3.1.2 Discussion

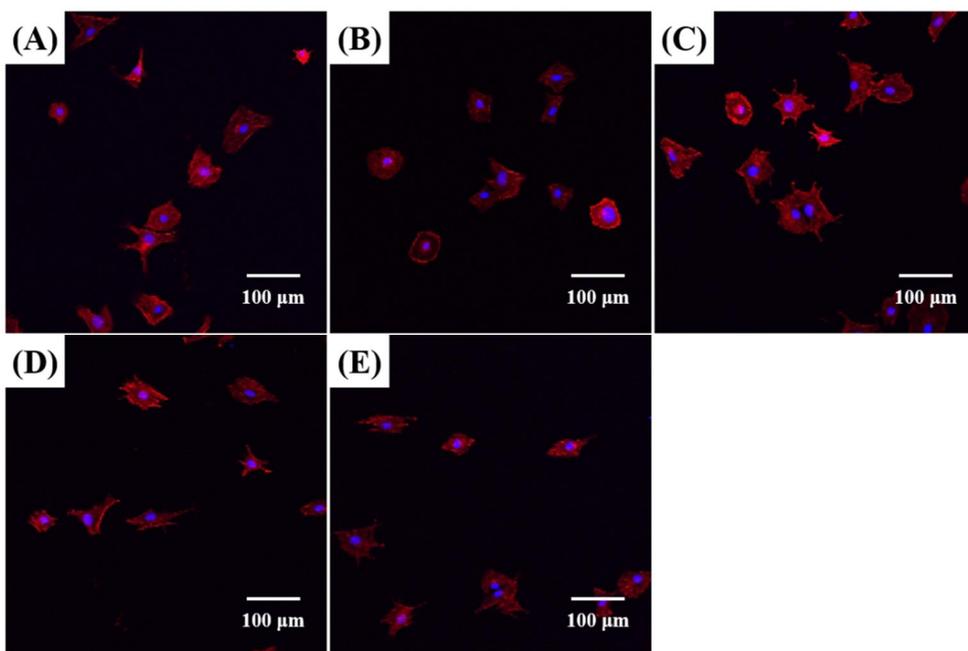

To evaluate the adhesive behavior of the preosteoblast on the surface of  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ ,  $\text{Ti}_2\text{AlN}$ , Ti-6Al-4V alloy, and pure Ti bulks, CLSM was employed. As observed in **Fig. 2.7**, the cells attached on all these materials very well. Compared with the Ti alloy and pure Ti, the spreading of preosteoblast on the MAX phase, particularly on the  $\text{Ti}_2\text{AlN}$  was promoted in the initial adhesion stage. Based on the 50 CLSM images (shown in **Fig. 2.8** and **Fig. 2.9**), the cell spreading area on the  $\text{Ti}_2\text{AlN}$  calculated using the *ImageTool 3.0* was  $2901 \mu\text{m}^2/\text{cell}$ , which was larger than that on the Ti alloy ( $2372 \mu\text{m}^2/\text{cell}$ ) or pure Ti ( $2450 \mu\text{m}^2/\text{cell}$ ) (**Fig. 2.8**). Because the hydrophilic materials induced a higher level of the adhesion and spreading of the MC3T3-E1 cells, <sup>[110]</sup> the contact angle results with deionized water corroborated these findings. The more hydrophilic  $\text{Ti}_2\text{AlN}$  ( $37.0^\circ$ ) exhibited better initial cell attachment compared with the commercial Ti-6Al-4V alloy and pure Ti ( $52.9^\circ$  and  $51.6^\circ$  respectively, as shown in **Fig. 2.6**).

**Fig. 2.7.** Typical CLSM images used to determine the morphology of MC3T3-E1 cells attached on the surfaces of (A) Ti<sub>3</sub>AlC<sub>2</sub>, (B) Ti<sub>3</sub>SiC<sub>2</sub>, (C) Ti<sub>2</sub>AlN, (D) Ti-6Al-4V alloy, and (E) pure Ti specimens after incubation for 3 h. Phalloidin and DAPI were used to stain the filamentous actin (red) and nucleus (blue), respectively. The seeding cell density was  $1 \times 10^4$  cells/mL.

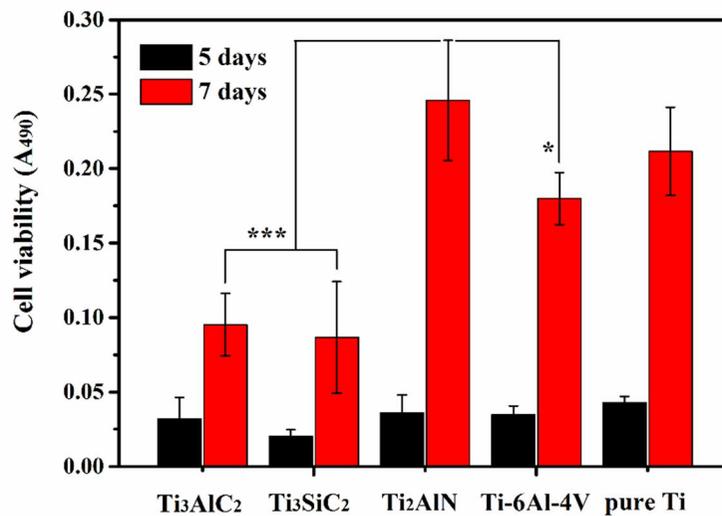

**Fig. 2.8.** Spreading areas of the preosteoblasts attached on the Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, Ti<sub>2</sub>AlN, Ti-6Al-4V alloy, and pure Ti specimens, which was obtained from the calculation of *ImageTool 3.0* using fifty CLSM images (**Fig. 2.9**) for each material at ×20 magnification. (\*\*p < 0.01)

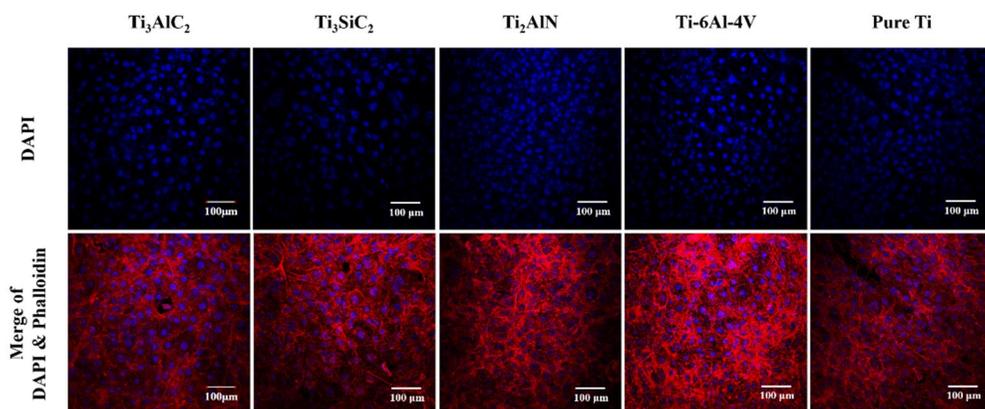

**Fig. 2.9.** Typical CLSM images used for calculating the spreading area of the preosteoblasts on the surfaces of **(A)**  $\text{Ti}_3\text{AlC}_2$ , **(B)**  $\text{Ti}_3\text{SiC}_2$ , **(C)**  $\text{Ti}_2\text{AlN}$ , **(D)** Ti-6Al-4V alloy, and **(E)** pure Ti specimens after incubation for 3 h. Phalloidin and DAPI were used to stain the filamentous actin (red) and nucleus (blue), respectively. The seeding cell density was  $1 \times 10^4$  cells/mL.

The viability of the preosteoblasts was then characterized by MTS assay and direct CLSM observation. Based on **Fig. 2.10**, the MAX phase exhibited non-toxicity on the preosteoblast, and the cells actively proliferated on all the materials. Among the selected MAX phases,  $\text{Ti}_2\text{AlN}$  exhibited the best performance

based on the optical density value. Moreover, the cell viability in the  $Ti_2AlN$  group was even higher than that in the commercial  $Ti-6Al-4V$  alloy and was comparable to that in the pure  $Ti$  after 7 days of incubation. This phenomenon was also supported by the distribution of the preosteoblasts directly observed using CLSM images (**Fig. 2.11**). In contrast to  $Ti_3AlC_2$ ,  $Ti_3SiC_2$ , and  $Ti-6Al-4V$  alloy, a larger number of preosteoblasts was universally distributed on the  $Ti_2AlN$ .

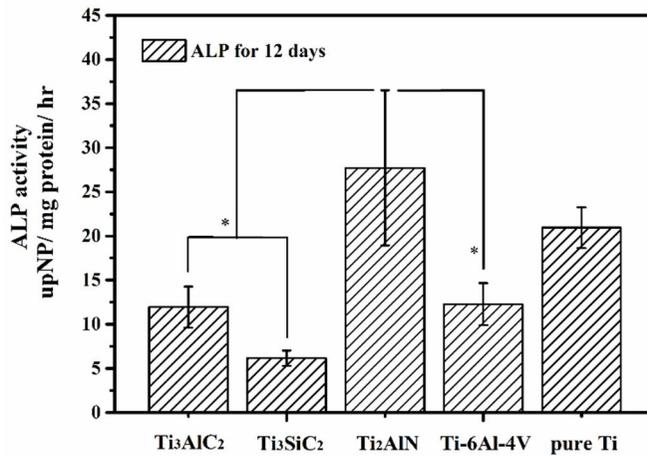

**Fig. 2.10.** MTS assay for determining the cell viability of MC3T3-E1 cells on the  $Ti_3AlC_2$ ,  $Ti_3SiC_2$ ,  $Ti_2AlN$ ,  $Ti-6Al-4V$  alloy, and pure  $Ti$  specimens after 5-day and 7-day incubation. The seeding cell density was  $1 \times 10^4$  cells/mL. (\* $p < 0.05$ , \*\*\* $p < 0.001$ )

**Fig. 2.11.** Typical CLSM image used to determine the corresponding distribution of MC3T3-E1 cells grown after 7 days. Phalloidin and DAPI were used to stain the filamentous actin (red) and nucleus (blue), respectively. The seeding cell density was  $1 \times 10^4$  cells/mL.

During the osteoblastic differentiation, ALP was formed to promote the hydrolysis of phosphate esters, which was used as an early marker to determine the differentiation degree of preosteoblasts. <sup>[122, 123]</sup> In this study, the ALP activity of the MC3T3-E1 cells cultured on the surfaces of  $Ti_3AlC_2$ ,  $Ti_3SiC_2$ ,  $Ti_2AlN$ , Ti-6Al-4V alloy, and pure Ti for 12 days was recorded using microplate reader (**Fig. 2.12**). Among the selected MAX phases, the ALP activity in the  $Ti_2AlN$  group was significantly higher than that in the other two phases. The ALP activity in the  $Ti_2AlN$  group was almost twofold and fourfold of that in the  $Ti_3AlC_2$  and  $Ti_3SiC_2$

group, respectively. Although a noticeable difference of the ALP activity between  $Ti_2AlN$  group and pure Ti group was difficultly detected, the osteogenic differentiation of preosteoblasts in the  $Ti_2AlN$  group was superior to that in the commercial Ti-6Al-4V alloy group.

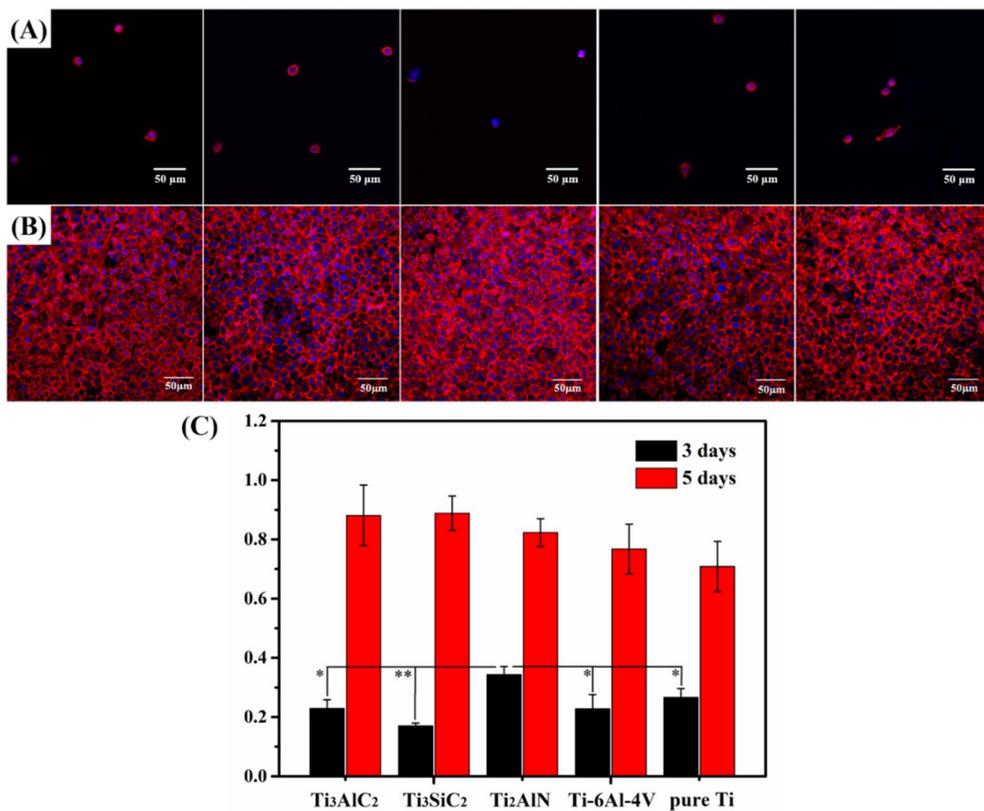

**Fig. 2.12.** ALP activity used to determine the differentiation of MC3T3-E1 cells after 12-day incubation on the  $Ti_3AlC_2$ ,  $Ti_3SiC_2$ ,  $Ti_2AlN$ , Ti-6Al-4V alloy, and pure Ti specimens. The seeding cell density was  $1 \times 10^4$  cells/mL. (\* $p < 0.05$ )

### 2.3.2 Biological Behaviors of Fibroblasts on the MAX Phases

Soft tissue is another important service condition during the dental implantation surgery. Herein, the mouse fibroblast cell line (L929; derivative of strain L) was employed to evaluate the biocompatibility of MAX phases under the soft tissue condition. The fibroblasts were cultured using the same method as that for the preosteoblasts except the culture medium added with 5% FBS. The procedures for cell adhesion and proliferation were also the same as those shown in 2.2.1.1.

The typical CLSM images in the **Fig. 2.13A** showed that the similar cell adhesive behaviors emerged on the  $Ti_3AlC_2$ ,  $Ti_3SiC_2$ ,  $Ti_2AlN$ , Ti-6Al-4V alloy, and pure Ti specimens after seeding for 3 h. The cell proliferation determined from the MTS assay and CLSM images also revealed a little difference (**Fig. 2.13B-C**). The mean values of each group obtained from the MTS assay at 5 days were at similar levels and the error bars overlapped. However, during the initial incubation stage (approximately 3 days), the fibroblasts proliferated faster on the  $Ti_2AlN$  than on the other phases. These phenomena could be ascribed to the strong viability of the fibroblasts, whose proliferation rate was almost three times than that of the osteoblasts. <sup>[124]</sup> It was very difficult to distinguish the slight differences between

these materials. In other words, the biocompatibility of these MAX phases was as good as the references, Ti-6Al-4V alloy and pure Ti, under fibroblastic condition.

**Fig. 2.13.** Biological behaviors of L929 cells on the Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, Ti<sub>2</sub>AlN, Ti-6Al-4V alloy, and pure Ti specimens: (A) Morphology and distribution of L929 cells after incubation for 3 h; (B-C) Cell proliferation determined from CLSM image (7 days) and MTS assay after 3-day and 5-day incubation. Phalloidin and DAPI were used to stain the filamentous actin (red) and nucleus (blue), respectively.

The seeding cell density was  $1 \times 10^4$  cells/mL. (\*p < 0.05, \*\*p < 0.01)

## 2.4 Theoretical Calculation of $\text{Ca}^{2+}$ Ions Absorbed on the MAX Phases

The  $\text{Ca}^{2+}$  ion plays a prominent role bridging a net negative substrate and anionic protein (integrin) for cell attachment. <sup>[111]</sup> The deposition of calcium is the first step for the nucleation of the calcium phosphate, which is critical for the implants in contact with the bony tissue. <sup>[114, 115]</sup> Hence, the simulation of the process of the  $\text{Ca}^{2+}$  adsorbed on the substrate can be used to evaluate the biocompatibility of the biomaterials. This typical process not only simplifies the diverse and complex biological interactions, but also reduces the workload for the calculation. For instance, the negative charge is calculated to confirm this process in the works of  $\text{TiO}_2$  and  $\text{TiN}$ . <sup>[114, 115]</sup> Herein, a new quantitative indicator (the binding energy of the absorbed  $\text{Ca}^{2+}$  ions with the substrate) is used to directly evaluate this absorption process since the surfaces of MAX phases ( $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ ,  $\text{Ti}_2\text{AlN}$ ) have been proven to have the negative charge in the normal pH range of body fluids according to the analysis of zeta potential. <sup>[125-128]</sup>

In this section, the first-principles calculations were performed to investigate the phenomenon of the  $\text{Ca}^{2+}$  ion bound on these selected MAX phases with the CASTEP package. <sup>[129]</sup> The general strategy was as follows: **(1)** Simplify the

surficial structures of MAX phases by selecting the stable representative surfaces; **(2)** Establish the partially oxidized the surficial structure; **(3)** Optimize the process of the  $\text{Ca}^{2+}$  ion absorbed on the above partially oxidized surfaces. In details, the ultrasoft pseudopotentials <sup>[130]</sup> and the plane-wave basis were adopted for the spin-polarized density functional theory computation. A kinetic-energy cutoff for plane-wave expansion was set to 420 eV in our calculations. The generalized gradient approximation (GGA) was expressed by the Perdew–Burke–Ernzerhof (PBE) functional for the exchange-correlation potential. <sup>[131, 132]</sup> The effect of van der Waals (vdW) interactions based on the PBE functional was included explicitly using the empirical correction scheme of Grimme. <sup>[133]</sup> The vacuum distance was set to 16 Å along the z direction to avoid the artificial interlayer interaction caused by periodic boundary condition. All the atoms in the unit cell were fully relaxed until the convergence criterion on each atom was less than  $10^{-5}$  eV in energy and 0.03 eV Å<sup>-1</sup> in force. The Brillouin zones were sampled with a 9×9×1 k-point grid using Monkhorst–Pack scheme. <sup>[134]</sup>

## 2.4.1 Establishment of Surface Structure of the Partially Oxidized MAX Phases

In the light of the layered hexagonal microstructure of MAX phases, the (100) and (001) surfaces were selected as representative surfaces based on the experimental XRD data (Fig. 2.14). To assess the stability of the naked surface slab, we first computed the cohesive energy ( $E_c$ ) of the (100) and (001) surface slabs, which was defined as:

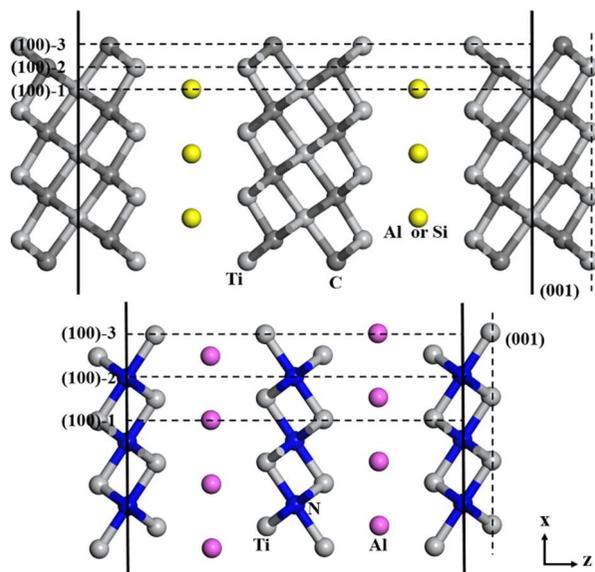

$$E_c = (E_{slab} - n_{Ti}E_{Ti} - n_{Al/Si}E_{Al/Si} - n_{N/C}E_{N/C})/n_{tot},$$

where  $E_{slab}$ ,  $E_{Ti}$ ,  $E_{Al/Si}$ , and  $E_{N/C}$  were the total energies of a surface slab, single Ti atom, single Al or Si atom and single N or C atom, respectively, and  $n_{tot}$ ,  $n_{Ti}$ ,  $n_{Al/Si}$ , and  $n_{N/C}$  were the total number of atoms and the respective number of Ti, Al (or Si) and N (or C) atoms in the supercell. To further evaluate the stability of the formation of the naked surface slabs relative to the simple stable substances, we defined the formation energy as:

$$E_f = (E_{slab} - n_{Ti}\mu_{Ti} - n_{Al/Si}\mu_{Al/Si} - n_{N/C}\mu_{N/C})/n_{tot},$$

where the chemical potentials  $\mu_{Ti}$ ,  $\mu_{Al/Si}$ , and  $\mu_{N/C}$  were defined as the energies per atom in bulk Ti, bulk Al or Si, and a nitrogen molecule or graphite, respectively.

$E_c$  and  $E_f$  of these surface slabs are listed in **Table 2.2**.

**Fig. 2.14.** Different configurations of the (100) and (001) surfaces for the  $Ti_3AlC_2$ ,  $Ti_3SiC_2$ , and  $Ti_2AlN$ .

All the bare (001) surfaces were the most stable and the easiest to be observed experimentally because they had the lowest  $E_c$  and  $E_f$  (**Fig. 2.1** and **Table 2.2**). However, for the bare (100) surface, there were three possible configurations for the MAX phases. As shown in **Fig. 2.14** and **Table 2.2**, the (100)-3 configuration could be transformed into the (100)-1 configuration for  $Ti_2AlN$ , because the single-coordinated Ti atom was unstable and readily reacted with water or oxygen. However, the single-coordinated Ti atom also tended to be removed from the

surface of the (100)-2 configuration to form a planar TiC surface, which was similar to the structure of the (100)-1 configuration for the  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$  after exposure to oxygen or water. Thus, the (100)-1 and (100)-2 configurations of  $\text{Ti}_2\text{AlN}$  and the (100)-1 and (100)-3 configurations of both  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$  were selected to investigate the following adsorption of the  $\text{Ca}^{2+}$  ion on the (100) surface.

**Table 2.2.** Cohesive energy ( $E_c$ ) and formation energy ( $E_f$ ) of the naked surface slabs of MAX phases for each configuration shown in **Fig. 2.14**.

surface	$E_c$ eV/atom	$E_f$ eV/atom	surface	$E_c$ eV/atom	$E_f$ eV/atom
TAC001	-7.31	-0.71	TSC100-3	-6.78	-0.15
TAC100-1	-6.58	-0.26	TAN001	-6.45	-1.17
TAC100-2	-6.55	-0.20	TAN100-1	-5.95	-0.79
TAC100-3	-6.63	-0.15	TAN100-2	-5.99	-0.88
TSC001	-7.47	-0.75	TAN100-3	-5.85	-0.63
TSC100-1	-6.66	-0.19	rTiO <sub>2</sub> 110	-	-
TSC100-2	-6.62	-0.026			

TAC, TSC and TAN represent  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$  and  $\text{Ti}_2\text{AlN}$ , respectively, in this table.

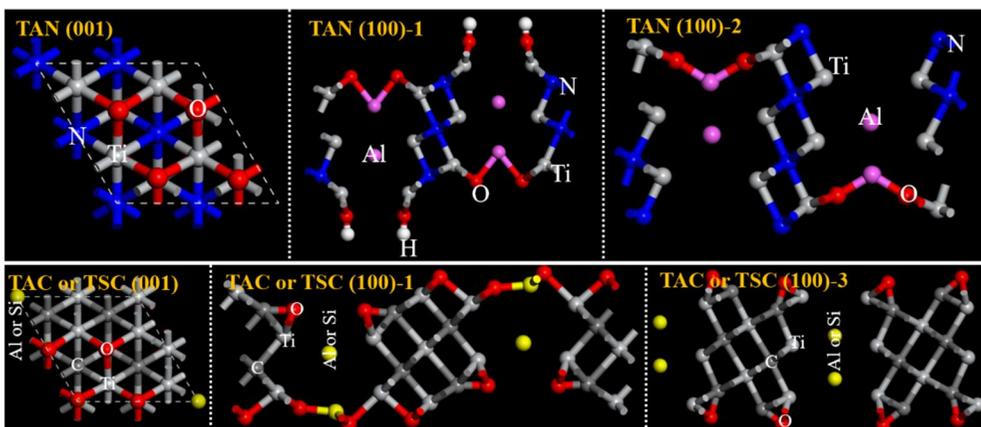

The MAX phase should be passivated by an oxidation reaction on the surface in ambient atmosphere. <sup>[135]</sup> From our experimental tests, the presence of the oxygen on the surface of MAX phases were also confirmed by the analyses of XPS and EDS (**Table 2.1** and **Fig. 2.3-2.5**). This phenomenon was widespread in the other titanium-based ceramics. For instance, Piskanec et al. reported that a partially oxidized TiN surface can be used as a preferential site for the deposition of Ca<sup>2+</sup> ion. <sup>[114]</sup> Herein, we tested various possible partially oxidized configurations followed by atomic relaxations.

The optimized stable configurations of Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, and Ti<sub>2</sub>AlN were presented in **Fig. 2.15**. The O atom was bound to three Ti atoms located above the N/C atom in the (001) configuration. Herein, the O atom was probably bound with the H atom to form a hydroxyl group (OH). However, this process was energetically unfavorable according to the formation energy, where

$$(F = E_{slab+mO+nH} - E_{slab+mO} - n\mu_H) > 0$$

especially under alkaline conditions. For the (100)-1 configuration of Ti<sub>2</sub>AlN, the

bridging OH group ( $F = -0.43$  eV) was coordinated by two Ti atoms bound to two N atoms, whereas the threefold-coordinated O atom was coordinated by one Al atom and two Ti atoms bound to three N atoms. Rodriguez et al. have shown that the CTiTi hollow is the most stable site for the adsorption of O atoms on the TiC (001) surface.<sup>[136]</sup> In addition, for the (100)-1 configurations of  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$ , one O atom was coordinated by two Ti atoms bound to three C atoms and by one C atom bound to five Ti atoms on the planar TiC surface, which was consistent with reports of Rodriguez et al. The other free surficial Ti and Al atoms were bound to the threefold-coordinated O atoms. The oxidation behaviors of the (100)-2 configuration for  $\text{Ti}_2\text{AlN}$  and the (100)-3 configuration for  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$  were similar to that of the (100)-1 configuration, in which the O atom was also bound to two Ti atoms and an Al atom for  $\text{Ti}_2\text{AlN}$  and the CTiTi hollow for  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$ , respectively (as observed in **Fig. 2.15**).

**Fig. 2.15.** Optimized configurations for partially oxidized surfaces of the  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$ .

## 2.4.2 Optimization of Absorption of $\text{Ca}^{2+}$ Ions

**Table 2.3.**  $\Delta E_{\text{bind}}$  of the  $\text{Ca}^{2+}$  ions bound on the different positions for each configuration shown in **Fig. 2.16** and **Fig. 2.17**.

Surface	Position 1	Position 2	Position 3	Position 4
TAC001	<u>-19.14</u>			
TAC100-1	-14.45	<u>-16.28</u>	-16.03	
TAC100-3	<u>-15.90</u>	-15.05		
TSC001	<u>-19.96</u>			
TSC100-1	-13.98	<u>-16.94</u>	-14.95	
TSC100-3	<u>-15.63</u>	-14.80		
TAN001	<u>-24.71</u>			
TAN100-1	-15.40	<u>-18.53</u>	-16.39	-16.02

TAN100-2	<b><u>-15.74</u></b>	-14.43
rTiO <sub>2</sub> 110	<b><u>-21.83</u></b>	

TAC, TSC and TAN represent Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub> and Ti<sub>2</sub>AlN, respectively, in this table. The  $\Delta E_{\text{bind}}$  for optimal position is marked with bold and underline. Unit: eV/atom

We also tested the possible adsorption sites of Ca<sup>2+</sup> ions on the surface of partially oxidized configurations of Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, and Ti<sub>2</sub>AlN (shown in **Table 2.3** and **Fig. 2.16-2.17**). The preferred adsorption site of Ca<sup>2+</sup> ions on the surface and the corresponding binding energy were shown in **Fig. 2.18** and **Table 2.3 (the bold values)**. The binding energy was defined as:

$$\Delta E_{\text{bind}} = (E_{\text{poMAX+mCa}^{2+}} - E_{\text{poMAX}} - mE_{\text{Ca}^{2+}})/m$$

where  $E_{\text{Ca}^{2+}}$ ,  $E_{\text{poMAX}}$ , and  $E_{\text{poMAX+mCa}^{2+}}$  represented the total energies of a single Ca<sup>2+</sup> ion, the specific partially oxidized surface of the MAX phase, and the corresponding configuration after Ca<sup>2+</sup> ions absorbed on this surface, respectively.  $m$  was the number of absorbed Ca<sup>2+</sup> ions.

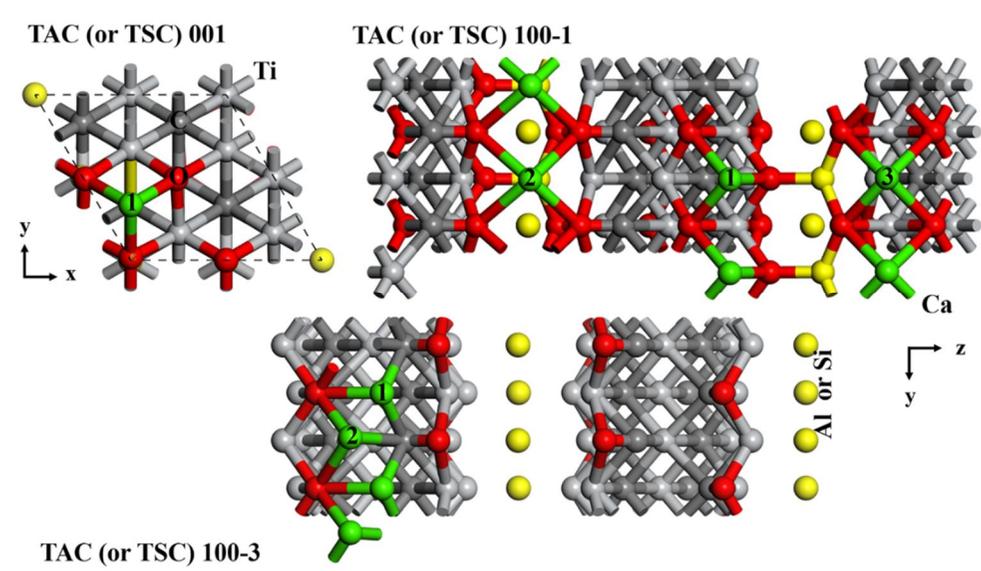

In the (001) configuration, the Ca<sup>2+</sup> ion was coordinated by three O atoms (**Fig. 2.18**). The binding energies of the Ca<sup>2+</sup> ion on the (001) configurations of Ti<sub>3</sub>AlC<sub>2</sub>, Ti<sub>3</sub>SiC<sub>2</sub>, and Ti<sub>2</sub>AlN were -19.14, -19.96, and -24.71 eV/atom, respectively. In

addition, the  $\text{Ca}^{2+}$  ion was coordinated by four O atoms in the (100)-1 configuration (**Fig. 2.18**), and the binding energies were  $-16.28$ ,  $-16.94$ , and  $-18.53$  eV/atom for  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$ , respectively. For the (100)-2 configuration of  $\text{Ti}_2\text{AlN}$ , the  $\text{Ca}^{2+}$  ion tended to bind to two threefold-coordinated N atoms with a binding energy of  $-15.74$  eV/atom, whereas the  $\text{Ca}^{2+}$  ion preferred to bind to two C atoms and one O atom in the (100)-3 configuration with binding energies of  $-15.90$  ( $-15.63$ ) eV/atom for  $\text{Ti}_3\text{AlC}_2$  ( $\text{Ti}_3\text{SiC}_2$ ), respectively (**Fig. 2.18**). For comparison, we studied the adsorption of  $\text{Ca}^{2+}$  ions on a rutile  $\text{TiO}_2$  (110) surface, which was the most stable representative surface of  $\text{TiO}_2$  [115]. The  $\text{Ca}^{2+}$  ion was coordinated by two bridging O atoms and two terminal O atoms of the OH group, which was consistent with the result of Svetina's work [115]. The binding energy was  $-21.83$  eV, which was considered the source of the good biocompatibility of the  $\text{TiO}_2$ .

In summary, the partially oxidized (001) surface of the  $\text{Ti}_2\text{AlN}$  exhibited a stronger affinity to the  $\text{Ca}^{2+}$  ion, in contrast with that of  $\text{TiO}_2$ . However, the binding strength of the  $\text{Ca}^{2+}$  ion on the partially oxidized (100) surfaces of  $\text{Ti}_2\text{AlN}$  and the (001) and (100) surfaces of both  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$  were weaker than that on  $\text{TiO}_2$ . These results indicated that the partially oxidized  $\text{Ti}_2\text{AlN}$  exhibited improved biocompatibility with respect to the partially oxidized  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$ , and

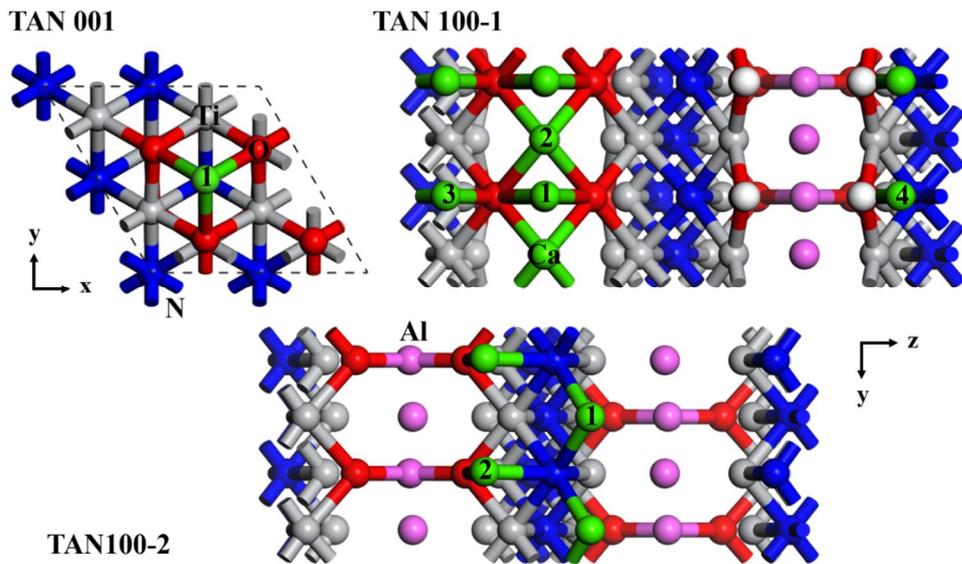

comparable biocompatibility to the pure Ti, which was in excellent agreement with the experimental observations.

It was worth the whistle that the binding energy of  $\text{Ca}^{2+}$  ion on the (001) surface was much stronger than that on the (100) surface for each MAX phase (**Table 2.3**). This phenomenon indicated that the MXenes ( $\text{Ti}_3\text{C}_2\text{T}_z$  and  $\text{Ti}_2\text{NT}_z$ ), which mainly were composed of the (001) surfaces, had a good affinity to the  $\text{Ca}^{2+}$  ion, and also the biocompatibility.

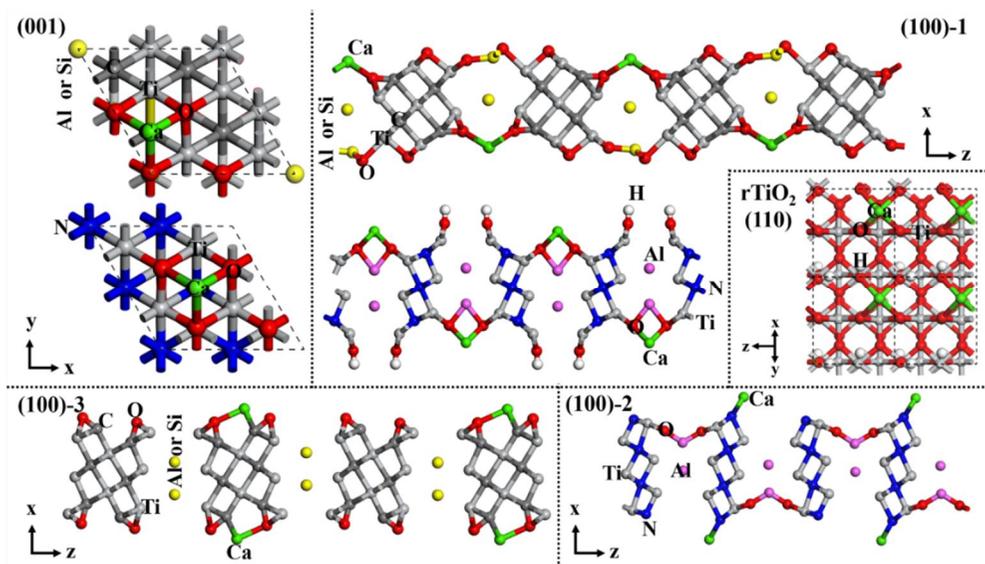

**Fig. 2.16.** Schematic diagram of the possible positions that the  $\text{Ca}^{2+}$  ions (green spheres) bound on the  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$ . (TAC and TSC represent  $\text{Ti}_3\text{AlC}_2$  and

Ti<sub>3</sub>SiC<sub>2</sub>, respectively)

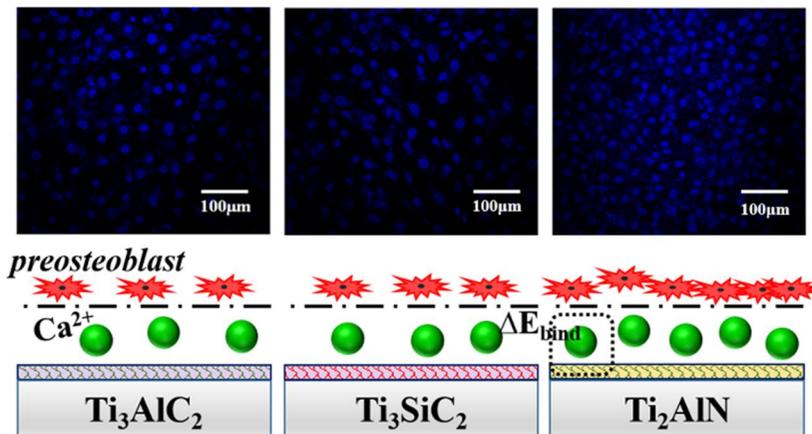

**Fig. 2.17.** Schematic diagram of the possible positions that the Ca<sup>2+</sup> ions (green spheres) bound on the Ti<sub>2</sub>AlN. (TAN represents Ti<sub>2</sub>AlN)

**Fig. 2.18.** Optimized configurations for the  $\text{Ca}^{2+}$  ion bound on the (001), (100)-1, (100)-2, and (100)-3 surfaces of the  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$  and the (110) surface of  $\text{rTiO}_2$ .

## 2.5 Mechanism for Biocompatibility of the MAX Phases.

**Fig. 2.19.** Schematic diagram of mechanism on the biocompatibility of  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$  based on the absorbed  $\text{Ca}^{2+}$  ions.

The cell affinity is known to be affected by the surface hydrophilicity, chemical composition, net charge, topography, and other biochemical-physical properties. <sup>[108,</sup>  
<sup>109]</sup> Herein, we observed that not only the hydrophilicity but also the intrinsic features of the chemical elements played important roles in the biological behavior of these selected MAX phases (**Fig. 2.19**). Because the real compositions of  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$  and  $\text{Ti}_2\text{AlN}$  surface are composed of  $\text{Al}_2\text{O}_3$  and  $\text{TiC}_x\text{O}_y$ ,  $\text{SiO}_2$  and  $\text{TiC}_x\text{O}_y$ , and  $\text{Al}_2\text{O}_3$  and  $\text{TiN}_x\text{O}_y$ , respectively <sup>[114, 119, 121]</sup> (**Fig. 2.3-2.5** and **Table 2.1**), and the surface of pure Ti and Ti-6Al-4V alloy are protected by  $\text{TiO}_2$ , and  $\text{TiO}_2$  and  $\text{Al}_2\text{O}_3$ ,

<sup>[137, 138]</sup> the different biocompatibility of these materials can be explained based on the different biological properties of these oxides, carbides and nitrides. It is unquestionable that the TiO<sub>2</sub> has the best biocompatibility among these oxides. <sup>[139-141]</sup> However, TiC layer and TiN layer were shown to enhance the biocompatibility of Ti-6Al-4V alloy <sup>[142]</sup>, NiTi alloy <sup>[113, 143]</sup>, and Co-Cr alloy <sup>[144]</sup>. In particular, the TiN layer even improved the biocompatibility of pure Ti <sup>[145]</sup> because the TiN layer not only physically prevented the release of toxic ions, such as vanadium and nickel ions, but also improved the cell functions, including promoting the adsorption of proteins, increasing the metabolism of energy and amino acids, and enhancing the regulation of inflammation. <sup>[113, 142, 143, 146]</sup>

To determine the source of the biocompatibility, the adsorption of Ca<sup>2+</sup> ions on the surface of the materials is commonly used in theoretical calculation. <sup>[114, 115]</sup> Stefano et al. demonstrated that the TiN<sub>x</sub>O<sub>y</sub> surface could initiate spontaneous nucleation of calcium phosphate because of the presence of a higher surface negative charge (TiO<sub>2</sub>, -0.45; the partially oxidized TiN, -0.80). <sup>[114]</sup> In our experiment, the binding energy between the absorbed Ca<sup>2+</sup> ion and the surface was first calculated using first-principles theory for direct evaluation. Compared with Ti<sub>3</sub>AlC<sub>2</sub> and Ti<sub>3</sub>SiC<sub>2</sub>, Ti<sub>2</sub>AlN had a notable stronger binding energy for the partially

oxidized (001) and (100) surfaces. The above analyses were consistent with our *in vitro* tests, in which  $\text{Ti}_2\text{AlN}$  exhibited preferable proliferation and osteogenic differentiation compared with  $\text{Ti}_3\text{AlC}_2$  and  $\text{Ti}_3\text{SiC}_2$ ; the performance was even superior to that of the commercial Ti–6Al–4V alloy and comparable to that of pure Ti.

This discovery is interesting, as previous studies on the MAX phase for biomedical applications have merely focused on  $\text{Ti}_3\text{SiC}_2$ ,<sup>[71, 72]</sup> which is considered to have the best resistance to oxidation and corrosion among the traditional MAX phases.<sup>[147, 148]</sup> However, this study revealed that the inertness was not the dominant factor determining the biocompatibility of the MAX phase. The  $\text{Ti}_2\text{AlN}$  exhibited outstanding biocompatibility because of the  $\text{TiN}_x\text{O}_y$  surface. The above analyses illustrated that the chemical composition of the MX layer in MAX phase played a more critical role than the A site atom. This mechanism also provided a direction to select a MAX phase for biomedical applications, which is valuable for such a large family. Based on this work, we speculate that the  $\text{Ti}_{n+1}\text{AlN}_n$  group (such as  $\text{Ti}_4\text{AlN}_3$ ) has excellent biocompatibility. It is also notable that the two-dimensional early transition metal carbides or nitrides (MXenes), mainly consisting of these (001) surfaces,<sup>[79, 81, 91]</sup> probably exhibit remarkable biocompatibility due to the strongest

binding energy of the  $\text{Ca}^{2+}$  ions on the (001) surface compared with the other surfaces.

## 2.6 Conclusion

This study used self-made pure MAX phase slices as platforms to evaluate the biocompatibility of  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$  via *in vitro* tests. All the phases were determined to be biocompatible with respect to the commercial Ti–6Al–4V alloy and pure Ti with preosteoblasts and fibroblasts. The cell proliferation and differentiation examination under an osteoblastic environment revealed that  $\text{Ti}_2\text{AlN}$  exhibited the optimal performance among these MAX phases; its performance was even superior to that of the commercial Ti–6Al–4V alloy and comparable to that of pure Ti. The mechanism for this behavior was interpreted for the different protective layers. First-principles calculations revealed that  $\text{Ca}^{2+}$  ions had a strong affinity for adsorption on the  $\text{TiN}_x\text{O}_y$  layer, which indicated the good biocompatibility of  $\text{Ti}_2\text{AlN}$ . Our discovery provides a new route for the selection of specific MAX phases and MXenes for biomedical applications.

## **Chapter 3.**

# **Strong and Biocompatible Poly (lactic acid) Membrane Enhanced by $\text{Ti}_3\text{C}_2\text{T}_z$ (MXenes) Nanosheets for Guided Bone Regeneration**

### 3.1 Introduction

Guided bone regeneration (GBR) is a reliable and validated therapy which is widely used in oral rehabilitation with the placement of dental implants and periodontal regeneration. <sup>[24-26]</sup> The basic principle of GBR technique is protecting the bone healing from the interference of non-osteogenic tissue using a GBR membrane <sup>[25-27]</sup>. Compared with non-resorbable titanium and polytetrafluoroethylene membranes, the resorbable membranes, such as poly (lactic acid) (PLA), poly (glycolic acid) (PGA), poly ( $\epsilon$ -caprolactone) (PCL) and their copolymers or tissue-derived collagens, are fascinating because of the exemption from the secondary surgery for membrane removal. <sup>[26, 29]</sup> However, the amount of regenerated bone is insufficient in the case of resorbable membrane, which results from the poor mechanical properties <sup>[29]</sup> and cellular responses. <sup>[26, 29]</sup>

Currently, graphene and its derivatives have been proved to enhance the mechanical properties of polymeric matrices, <sup>[34, 35, 43]</sup> and promote the interfacial bio-interaction, and mediate cellular signalling and biological performance with cocultured cells. <sup>[53-55]</sup> MXene ( $M_{n+1}X_nT_z$ ) is an emerging family of 2-dimensional

early transition metal carbides or nitrides, derived by the selective exfoliation of “A” layers from MAX phases (where M is an early transition metal, A is an A-group element, X is C and/or N, and  $T_z$  stands for terminated functional groups, such as -OH, -O, and -F).<sup>[56, 62, 79-81]</sup> These nanosheets possess large specific surface area, excellent electrical conductivity, and good hydrophilicity, which grant them desirable candidates for versatile applications such as in energy storage,<sup>[91, 93, 149, 150]</sup> surface absorbent,<sup>[94, 96]</sup> and sensor device<sup>[97, 98]</sup>. Very recently, the biomedical applications of MXenes including biosensing,<sup>[98, 100]</sup> anti-bacteria activity,<sup>[101, 102]</sup> photothermal ablation<sup>[103]</sup> and cellular imaging<sup>[105]</sup> arouse great interests.

The chapter 1 shows that MAX phases, the precursors of MXenes, possess good biocompatibility (**Fig. 2.16**). On the basis of the first-principles calculation from the binding energy of  $Ca^{2+}$  ion with the partially oxidized surficial layer, the (001) surfaces of each MAX phase, which the MXenes mainly consist of have much stronger cell affinity than the (100) surfaces (**Table 2.3**).

In this chapter, the intrinsic biocompatibility of MXene ( $Ti_3C_2T_z$  nanosheets, d- $Ti_3C_2T_z$ ) is discussed using graphene oxide (GO) as reference. Then, the commercial PLA is used as matrix of GBR membrane to explore the enhancement by  $Ti_3C_2T_z$  nanosheets (d- $Ti_3C_2T_z$ ) in respects of mechanical properties and

biocompatibility. To the best of our knowledge, this is the first effort to embed the MXenes into the biomedical polymer materials. The  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets, whose interface with hydrophobic PLA matrix is mediated using n-octyltriethoxysilane (OTES), endows the nanocomposite membranes with high mechanical properties and promotion of osteoblastic adhesion, proliferation, and differentiation.

## **3.2 Preparation and Characterization of d- $\text{Ti}_3\text{C}_2\text{T}_z$ and GO**

### **3.2.1 Preparation and Characterization of d- $\text{Ti}_3\text{C}_2\text{T}_z$**

#### **3.2.1.1 Methods**

The  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets (d- $\text{Ti}_3\text{C}_2\text{T}_z$ ) were prepared based on the previous references with chemical acid etching and physical sonication. <sup>[84, 91]</sup> In a typical procedure, **(1)** 2 g of  $\text{Ti}_3\text{AlC}_2$  powders (400 mesh, Beijing Jinhezhi Materials Co., Ltd., China) were carefully added into the 20 mL of hydrochloric acid (7.5 M) with 1.98 g of lithium fluoride (LiF, Alfa Aesar, 98.5%). The time of above procedure should be over 10 min to avoid the initial overheating of the solution as the result of exothermic reactions. **(2)** The mixture was stirred using a magnetic Teflon stir bar for 24 h at 35 °C. **(3)** The as-produced powders (exfoliated  $\text{Ti}_3\text{C}_2\text{T}_z$ , e- $\text{Ti}_3\text{C}_2\text{T}_z$ ) were

rinsed by hydrochloric acid (5 M) for 5 cycles to remove the excess LiF. **(4)** The deionized water was then used to remove the remaining hydrochloric acid until the pH of the supernatant reached approximately 6. The centrifuge (3500 rpm, 15 min; Hanil MF 550, Korea) was employed during above washing steps. **(5)** In order to prepare the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheets, the e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> powders were dispersed in deionized water with a weight ratio of e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>: water of 1:100 in vacuum chamber (200 Pa for 30 min). The suspension was then sonicated in an ultrasonic bath (40 % power; Daihan DH300H, Korea) under bubbling Ar flow for 1 h. **(6)** After centrifuged at 3500 rpm for 1 h, the supernatant, which contained the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was collected.

The Ti<sub>3</sub>AlC<sub>2</sub>, e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>, and d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> were characterized by the X-ray diffractometer (XRD, AXS D8 Advance, Bruker, Germany) with Cu K<sub>α</sub> radiation and their spectra were collected at a step scans of 0.02° 2θ and a step time of 0.2 sec. The morphology of e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was observed using field emission scanning electron microscope (Fe-SEM, ZEISS Merlin Compact, Germany). The morphology and structure of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> were characterized using transmission electron microscopy (TEM, Tecnai F20, FEI, USA) equipped with electron diffraction (ED) patterns, and atomic force microscope (AFM, Nano Xpert-II, EM4SYS, Korea).

### 3.2.1.2 Discussion

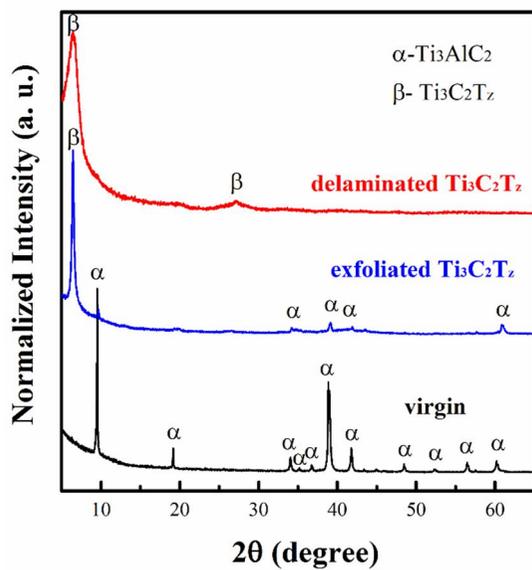

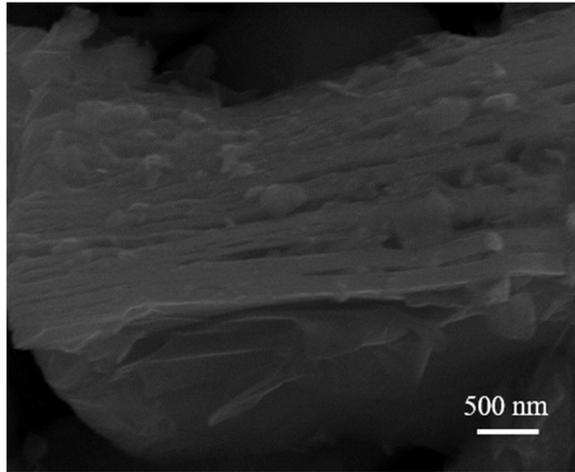

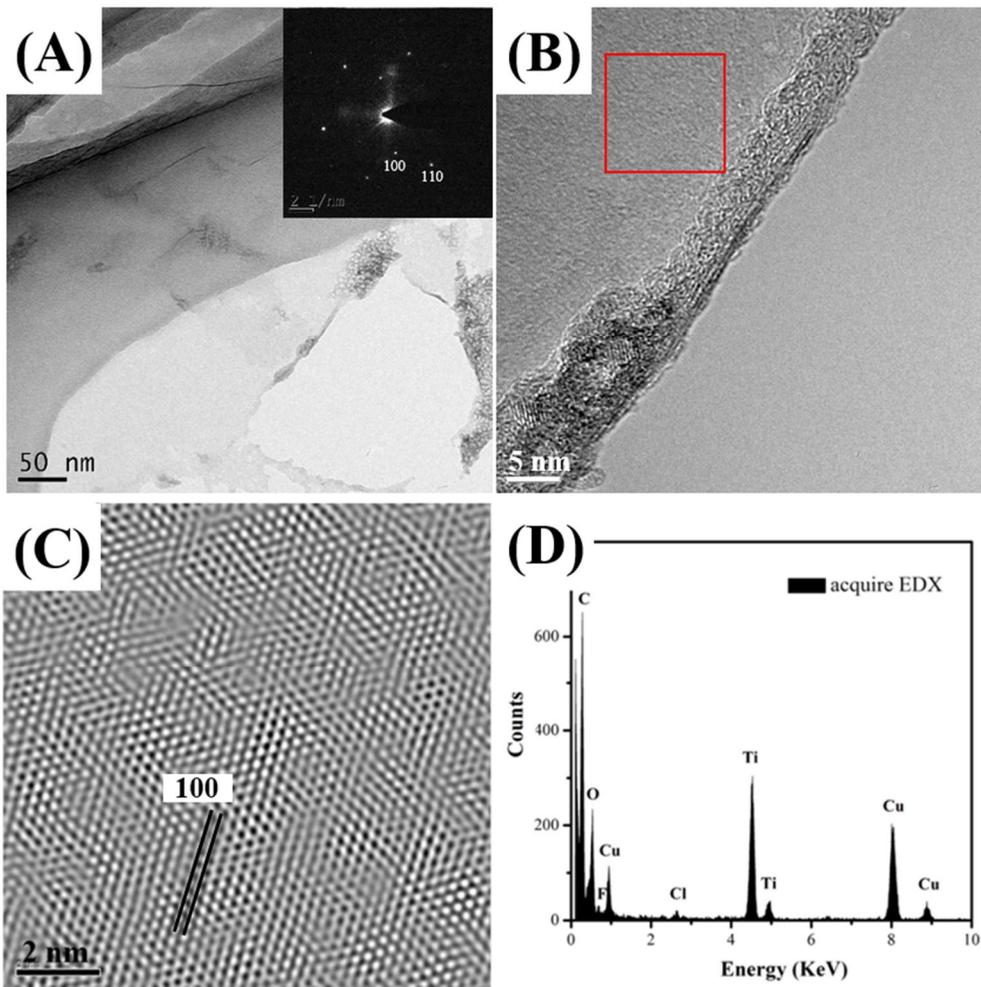

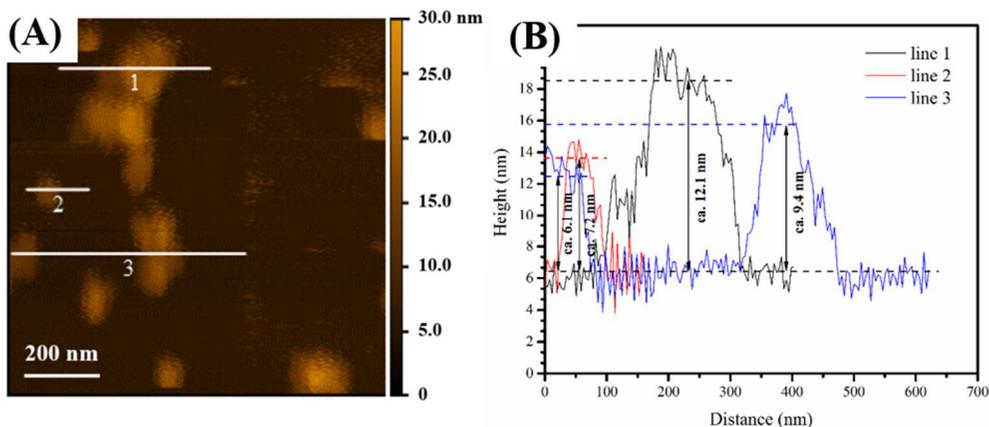

Fig. 3.1. XRD analysis of  $\text{Ti}_3\text{AlC}_2$ , e- $\text{Ti}_3\text{C}_2\text{T}_z$  and d- $\text{Ti}_3\text{C}_2\text{T}_z$  flakes.

**Fig. 3.2.** SEM image of the e-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>.

**Fig. 3.3.** TEM analysis of the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> flakes: **(A)** Overall morphology, inset, Nano beam electron diffraction (NBED); **(B)** High resolution transmission electron microscopy (HRTEM) image and curled edged, which exhibits the flake is very thin; **(C)** Inverse fast Fourier transform (IFFT) image; **(D)** Analysis results of energy dispersive spectrometer (EDS).

**Fig. 3.4.** (A) AFM image of the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> flakes; (C) Thickness of the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> flakes determined by AFM.

The preparation process of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheets was detected using XRD, SEM, TEM and AFM. The XRD patterns in the **Fig. 3.1** showed that most of the Ti<sub>3</sub>AlC<sub>2</sub> powders transformed to e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> after being etched in the LiF-HCl mixture for 24 h. There was no LiF or LiCl except a little Ti<sub>3</sub>AlC<sub>2</sub> observed in the XRD patterns, after the as-synthesized powders were washed by 5 M HCl aqueous solution and deionized water. However, these Ti<sub>3</sub>AlC<sub>2</sub> particles could be easily removed during the delamination of e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>, since the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheets were collected in the supernatant (3500 rpm for 1 h). In the XRD pattern of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>, only the peaks diffracted from the Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> were detected. The SEM image of e-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> exhibited accordion-like structure, which was the typical morphology

observed in the previous reference (**Fig. 3.2**).<sup>[79]</sup>

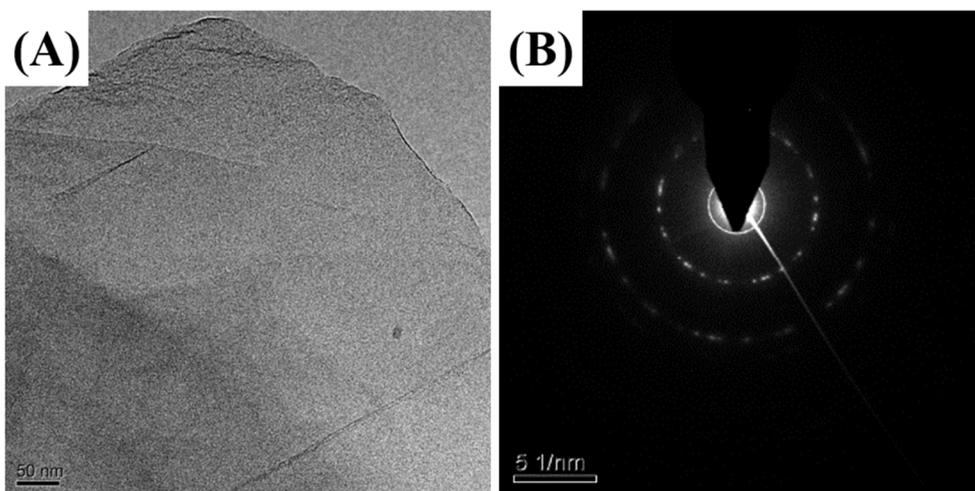

In order to further analyze the structure of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheets, the TEM equipped with ED was employed (**Fig. 3.3**). The size of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was around several hundred nanometers. The curled edges indicated that these nanosheets were very thin. The electron diffraction pattern from the nano electron beam showed typical hexagonal structure, whose space distance of (100) plane ( $d_{100}$ ) was 0.264 nm. This space distance could also be calculated from the Inverse Fast Fourier Transform (IFFT) image, which was 0.267 nm. These values were similar to the previous reference (0.266 nm).<sup>[81]</sup> The result of energy dispersive spectrometer (EDS) showed the signal of Ti, C, O, F, Cl, and Cu. The element of O, F, and Cl could be thought from the functional groups on the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>. While, the Cu came from the supporting mesh. The AFM was used to assist the analysis of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> (**Fig. 3.4**). The size of the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> could be more clearly observed (100 – 200 nm). In addition, the thickness of the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheet was about 6.1 – 7.2 nm, which consisted of 6 – 7 single layers of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>. All the above analyses demonstrated that the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was successfully fabricated using the exfoliation of chemical etching and delamination of physical sonication.

### 3.2.2 Preparation and Characterization of GO

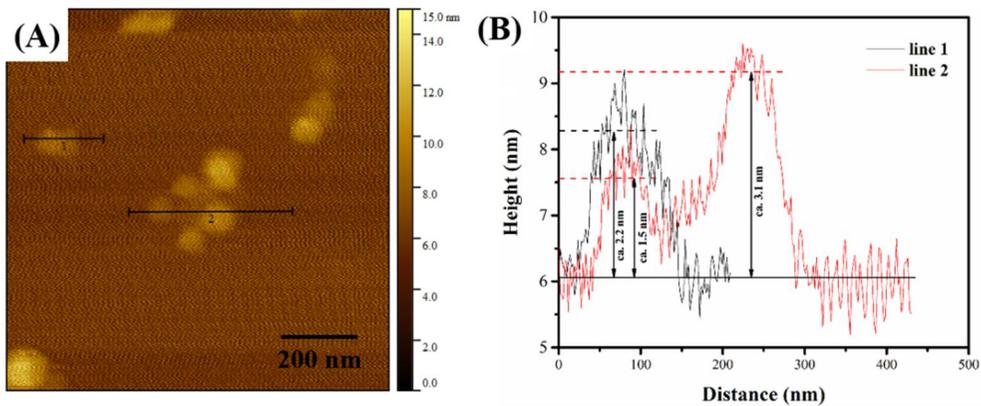

The GO nanosheets were prepared using modified Hummer's method according to the previous references. <sup>[151, 152]</sup> In brief, **(1)** 3 g of natural graphite powders and 2 g of NaNO<sub>3</sub> were mixed in a beaker (1 L) with an ice bath (< 4 °C), **(2)** followed by slow addition of 138 mL H<sub>2</sub>SO<sub>4</sub> (98 %) with stirring over the course of 20 min. **(3)** Then 18 g of KMnO<sub>4</sub> was carefully added into the above mixture. The ice bath was removed after another 15 min of stirring, and the mixture was continuously stirred for 12 h at room temperature. **(4)** Subsequently, the mixture was gradually diluted with 600 mL of warm deionized water (60 °C). **(5)** After stirred for 30 min, 20 mL of H<sub>2</sub>O<sub>2</sub> (37 %) was then added into the diluted solution and stirred for another 2 h to prevent the further oxidation of the GO. **(6)** The as-produced mixture was rinsed sequentially using HCl (5 %) and deionized water with centrifugation for 7 cycles, respectively. **(7)** The precipitate was re-dispersed in 600 mL of deionized water and sonicated with cell crusher for 4 h. **(8)** After the suspension was centrifuged at 11000 rpm for 15 min (Techcomp CT14D, China), the GO nanosheets were obtained from the supernatant along with freeze drying.

The GO nanosheets were characterized using transmission electron microscopy (TEM, Tecnai F20, FEI, USA) equipped with electron diffraction (ED) patterns, and atomic force microscope (AFM, Nano Xpert-II, EM4SYS, Korea).

From the TEM image, the size of GO nanosheets was about several hundred nanometers (**Fig. 3.5A**). The electron diffraction pattern shown in **Fig. 3.5B** consisted of two rings, which resulted from the stack of several GO nanosheets. The inner ring belonged to (100) and outer ring belonged to (110).<sup>[153]</sup> The AFM image showed that the size of GO nanosheets was around 100 nm, and the thickness was about 1.5 – 2.2 nm, which consisted of 2 – 3 single layers of GO (**Fig. 3.6**).

**Fig. 3.5.** (A) TEM overall morphology of the graphene oxide flakes; (B) Image of the selected area electron diffraction (SAED).

**Fig. 3.6.** (A) AFM image of the GO flakes; (C) Thickness of the GO flakes determined by AFM.

### 3.3 Comparison on Biocompatibility of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and GO

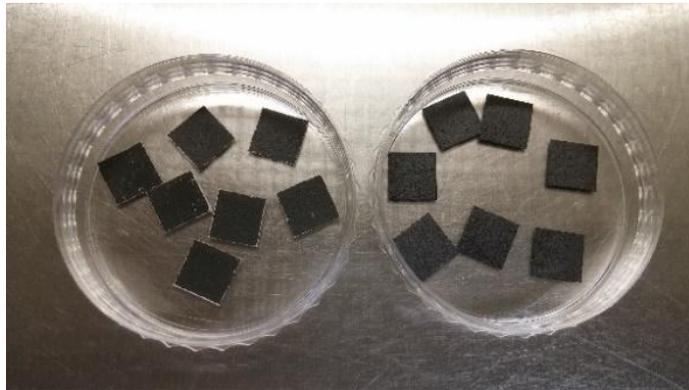

Although in the chapter 2, the theoretical calculation of binding energy of Ca<sup>2+</sup> ions absorbed on partially oxidized (001) surface of Ti<sub>3</sub>AlC<sub>2</sub> has been discussed to speculate the good biocompatibility of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>, the real intrinsic biocompatibility of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> is still unclearly. Herein, a mouse preosteoblast cell line is employed to evaluate the intrinsic biocompatibility of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> using GO as a reference, since the GO has the similar structure with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>, which is also granted by the hydrophilic functional group such as -O and -OH. In addition, the GO has been widely proved to accelerate the cell adhesion and proliferation, and induce the osteogenic differentiation.<sup>[53-55]</sup> The Teflon filters coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and GO are used as platform due to the convenience for *in vitro* tests.

#### 3.3.1 Preparation of Teflon Filters Coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and GO

The d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and GO nanosheets were separately deposited on the Teflon filters (0.22 μm, Haining Yibo, China) using vacuum filtration from their as-produced suspension. After dried overnight, the filters were trimmed to 1 cm × 1 cm slices (for cell adhesion and proliferation) and sectors with 4 cm<sup>2</sup> of area (for

cell differentiation). Before the *in vitro* tests, the specimens were disinfected by PBS for 5 cycles and UV for 30 min.

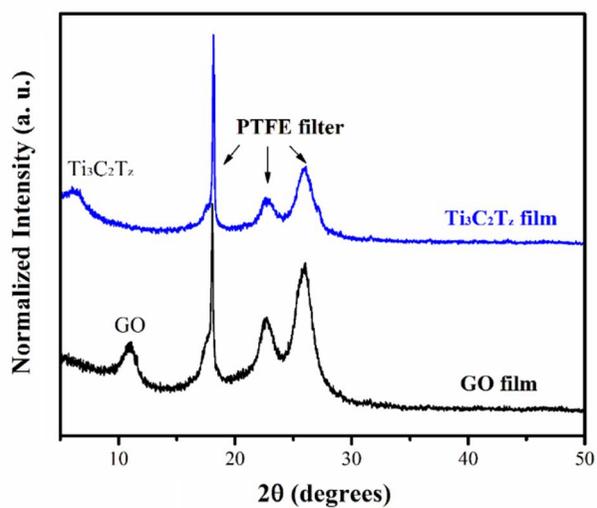

The optical images of Teflon filters coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and GO nanosheets were showed in **Fig. 3.7** and **Fig. 3.8**. From the XRD spectra, there was no impurity except the peaks belonging to the Teflon filter (**Fig. 3.9**).

**Fig. 3.7.** The optical images of Teflon filter coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> (left) and GO nanosheets (right) for cell adhesion and proliferation.

**Fig. 3.8.** The optical images of Teflon filters coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (left) and GO nanosheets (right) for cell differentiation.

**Fig. 3.9.** X-ray diffraction spectra of Teflon filters coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> and GO.

### **3.3.2 Biological Behaviors of Preosteoblasts on the Teflon Filters Coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and GO Nanosheets**

#### **3.3.2.1 Methods**

A mouse preosteoblast cell line (MC3T3-E1; ATCC CRL-2593, USA) was employed via *in vitro* tests. The cells were cultivated in alpha-minimum essential medium ( $\alpha$ -MEM, Welgene, Korea) with 10% fetal bovine serum (FBS; Cellgro, USA) and 1% penicillin streptomycin (Pen Strep; Life Technologies, USA) in a humidified incubator (Sanyo, Japan) with 5% CO<sub>2</sub> at 37°C. A dye-exclusion assay (Trypan blue) was used to count the cells.

The morphology and distribution of the preosteoblasts ( $5 \times 10^4$  cells/mL) after being cultured for 4 h were recorded using the confocal laser scanning microscopy (CLSM; Olympus FluoView FV1000, Japan). Phalloidin (Life Technology, USA) and 4', 6-diamidino-2-phenylindole (DAPI, Life Technology, USA) were used to stain the filamentous actin and nucleus, respectively. The SEM was also used to detect the spreading of preosteoblasts on the PLA membranes, where the adherent cells were fixed with 2.5% glutaraldehyde and dehydrated in graded ethanol.

The cell proliferation after 5-day and 7-day incubation ( $1 \times 10^4$  cells/mL), was analyzed based on the amount of DNA using a Cyquant cell proliferation assay kit (C7026, Invitrogen, USA). The DNA level of the detached cells was evaluated using a multiple plate reader (Victor3, Perkin Elmer, Germany) at 480/520 nm wavelength. The measured fluorescence values were converted to the DNA content using a DNA standard curve.

The cell differentiation was determined by the alkaline phosphatase (ALP) assay. After incubation for 12 days, the total protein of the cells was determined using the Bio-Rad protein assay kit (Bio-Rad, USA) based on a series of bovine serum albumin (BSA; Sigma) standards. Then, the ALP activity was predicted based on the color change from p-nitrophenyl phosphate (pNPP, Sigma) to p-nitrophenol (pNP). The amount of ALP was calculated based on the absorbance value at 405 nm (OD value) per milligram of total cellular protein.

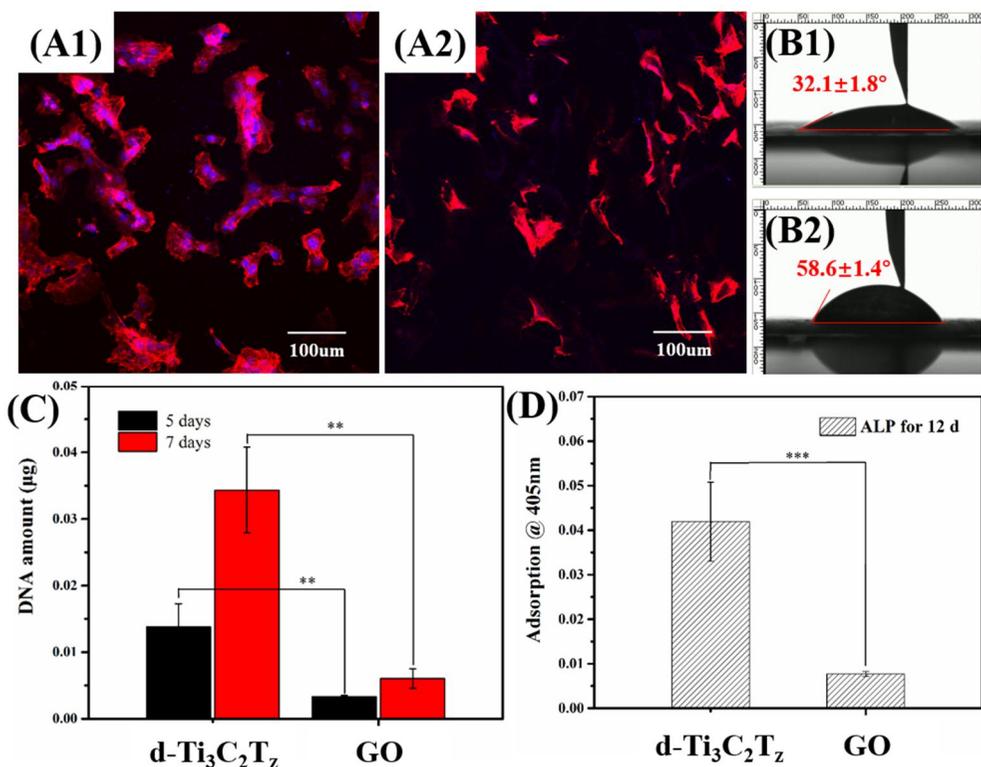

The hydrophilicity of the Teflon filter coated with d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and GO slices was evaluated based on the contact angle with approximately 10  $\mu$ L of deionized water using a goniometer (Phoenix 300, Korea) at ambient atmosphere.

All the results were expressed as the mean  $\pm$  standard deviation. The difference between the two groups was determined with a one-way analysis of variance

(ANOVA) using *Statistical Product and Service Solutions* software, and  $p < 0.05$  was considered to be statistically significant.

### 3.3.2.2 Discussion

As a prerequisite, the deduction of the intrinsic biocompatibility of  $\text{Ti}_3\text{C}_2\text{T}_z$  was first confirmed on account of the contrast with GO using mouse preosteoblast cell line (MC3T3-E1) (**Fig. 3.10**). The typical CLSM images showed that preosteoblasts spread much better on the  $\text{Ti}_3\text{C}_2\text{T}_z$ -coated surface than on the GO-coated surface (**Fig. 3.10A**). This phenomenon was corroborated by the results of contact angle with deionized water since the hydrophilic materials induced a higher level of the adhesion and spreading of the MC3T3-E1 cells.<sup>[110]</sup> The more hydrophilic d- $\text{Ti}_3\text{C}_2\text{T}_z$  ( $32.1^\circ$ ) exhibited better initial cell attachment compared with the GO ( $58.6^\circ$ , **Fig. 3.10B**). Moreover, the d- $\text{Ti}_3\text{C}_2\text{T}_z$  exhibited preferable cell proliferation and differentiation performance than GO, which were attested by DNA assay and alkaline phosphatase (ALP) assay, respectively (**Fig. 3.10C-D**). These results could be explained by the better biocompatibility of Ti-based materials compared with the C-based materials. For instance, Ti could be used to enhance the biocompatibility of polymers<sup>[154]</sup> and diamond-like carbon (DLC) coatings.<sup>[155]</sup>

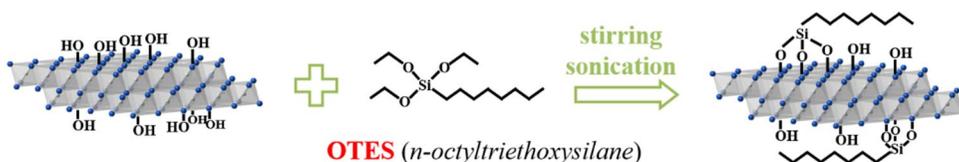

**Fig. 3.10.** The intrinsic biocompatibility of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (1) and GO (2): (A) Typical CLSM images of adherent MC3T3-E1 cells after incubation for 4 h. Seeding cell density was  $5 \times 10^4$  cells/mL; (B) The hydrophilicity determined by the contact angle with the deionized water; (C) The cell proliferation after 5-day and 7-day incubation determined by DNA assay. Seeding cell density was  $1 \times 10^4$  cells/mL. (\*\*P<0.01); (D) The cell differentiation after 12-day incubation determined by ALP activity. Seeding cell density was  $1 \times 10^4$  cells/mL. (\*\*P<0.01); (\*\*\*)P<0.001)

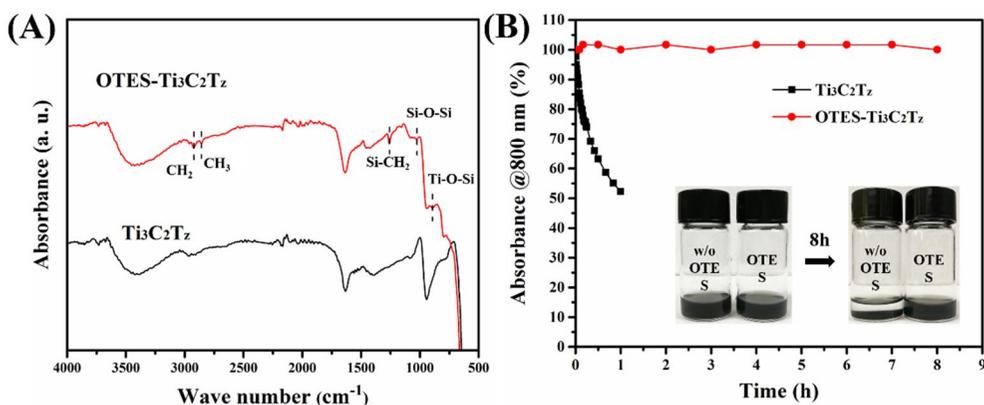

### 3.4 Preparation of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> Enhanced PLA Nanocomposite Membrane

#### 3.4.1 Surface Modification of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>

The interaction between the filler and matrix is the critical issue for the composite materials. <sup>[156]</sup> In this work, a biocompatible silane OTES <sup>[157]</sup> was used to mediate the hydrophilic d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and hydrophobic PLA (**Fig. 3.11**). In brief, **(1)** the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheets were separated from the aqueous suspension using ultrahigh-speed centrifuge (Hanil Micro 17TR, Korea) at 15000 rpm for 30 min. **(2)** After dried overnight, 80 mg of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheets were re-dispersed in the 40 mL of ethanol (containing 1 vol. % water) using sonication and magnetic stirring. **(3)** Then 1 vol. % OTES was added into the mixture and continuously stirred for 1 day. **(4)** After reaction, the excess OTES was rinsed using ultrahigh-speed centrifuge with ethanol for 5 cycles and **(5)** the OTES grafted d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> nanosheets (OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>) were obtained after dried overnight.

**Fig. 3.11.** Schematic diagram of surface modification of OTES on the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>.

**Fig. 3.12.** (A) FT-IR spectra of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (black) and OTES grafted d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (red). (B) The dispersity and stability of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (black) and OTES grafted d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (red) in the DCM determined by the relative absorbance of UV-visible spectrophotometer at 800 nm. Inset: digital images.

The Fourier transform infrared (FT-IR) spectra confirmed that the OTES was successfully grafted on d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (**Fig. 3.12A**). The identical stretching vibrations emerged in the both of spectra, including -OH at 3420 cm<sup>-1</sup>, C=O at 1640 cm<sup>-1</sup>, and O-H at 1400 cm<sup>-1</sup>, which belonged to Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>.<sup>[104, 158]</sup> Meanwhile, the new peaks appeared in the OTES-treated Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>.<sup>[159, 160]</sup> The peak of 2920 cm<sup>-1</sup> and 2860 cm<sup>-1</sup> belonged to the asymmetric and symmetric vibrations of C-H in the CH<sub>2</sub> and CH<sub>3</sub>. The peak of 1260 cm<sup>-1</sup> was generated from the vibration of C-H in the Si-CH<sub>2</sub>. The peaks of 1030 cm<sup>-1</sup> and 900 cm<sup>-1</sup> belonged to the Si-O-Si and Ti-O-Si, respectively.

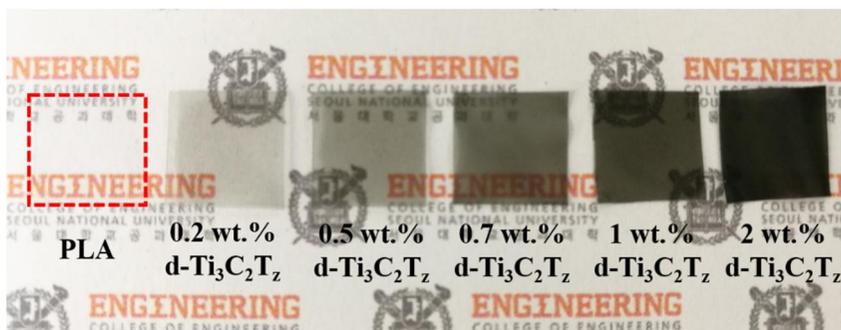

[159, 160] Furthermore, the dispersity and stability of the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> in the dichloromethane (DCM) was evaluated using the UV-visible spectrophotometer (at 800 nm, shown in **Fig. 3.12B**). The relative absorbance of the virgin d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/DCM suspension decreased to 50 % after holding for about 1 h. In contrast, the relative absorbance in the case of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/DCM suspension maintained around 100 % for up to 8 h. The digital images also clearly showed that the virgin d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/DCM suspension became transparent after holding for 8 h, while the OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/DCM suspension was still turbid (inset in **Fig. 3.12B**). All the above results demonstrated that the OTES grafted d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> had a good dispersity and stability in the hydrophobic DCM solvent.

### **3.4.2 Preparation of PLA Nanocomposite Membrane Using Solvent Casting**

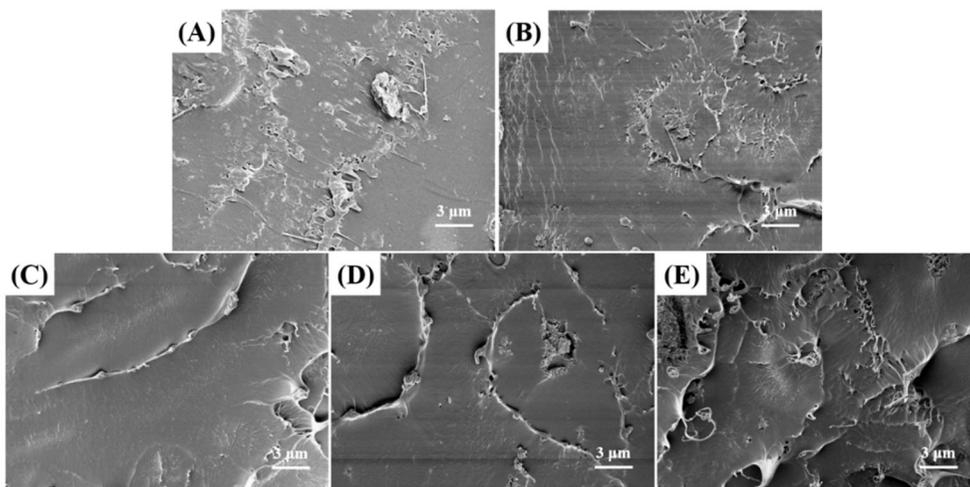

The OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> enhanced PLA composite membranes were prepared using solvent casting. In brief, the certain amount of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was dispersed in the dichloromethane (DCM) with sonication and magnetic stirring. Then the PLA beads (Pureco, Korea; M<sub>n</sub>: 70,000; M<sub>w</sub>: 140,000) were added into the mixture and stirred for 2 days. The ratio of DCM to PLA beads is 10 mL to 1 g. And the variable

ratio of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> to PLA was 0, 0.2 wt. %, 0.5 wt. %, 0.7 wt. %, 1 wt.% and 2 wt. %. Subsequently, the mixture suspension was poured into the polyethylene (PE) mold. After dried in the hood overnight (room temperature), the as-produced membranes were dried in the vacuum for another 1 day to clear all the remaining DCM. The pure PLA membrane was also prepared with the same method, which was used as reference for the following property tests.

The **Fig. 3.13** showed the OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> enhanced PLA nanocomposite membranes. They were uniform, and the transparency had a negative correlation with the loading content of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>. The morphology of cross section was characterized using field emission scanning electron microscope (**Fig. 3.14**). The nanocomposite membranes with low loading content of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> exhibited uniform morphology (up to 0.5 wt. %). However, these flakes aggregated together when the filler content increased (above 0.5 wt. %).

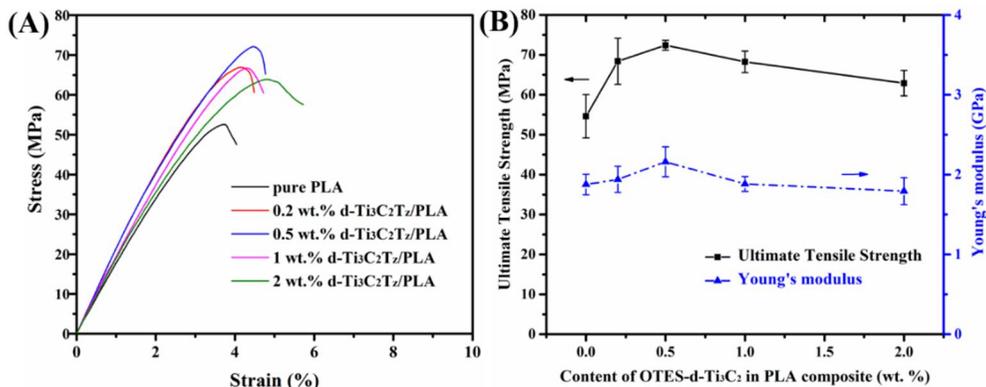

**Fig. 3.13.** Optical images of PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>/PLA composite membranes prepared using simple solvent casting.

**Fig. 3.14.** Typical SEM cross section morphology of pure PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>/PLA nanocomposite membranes with different loading content: (A) Pure PLA, (B) 0.2 wt. %, (C) 0.5 wt. %, (D) 1 wt. %, (E) 2 wt. %.

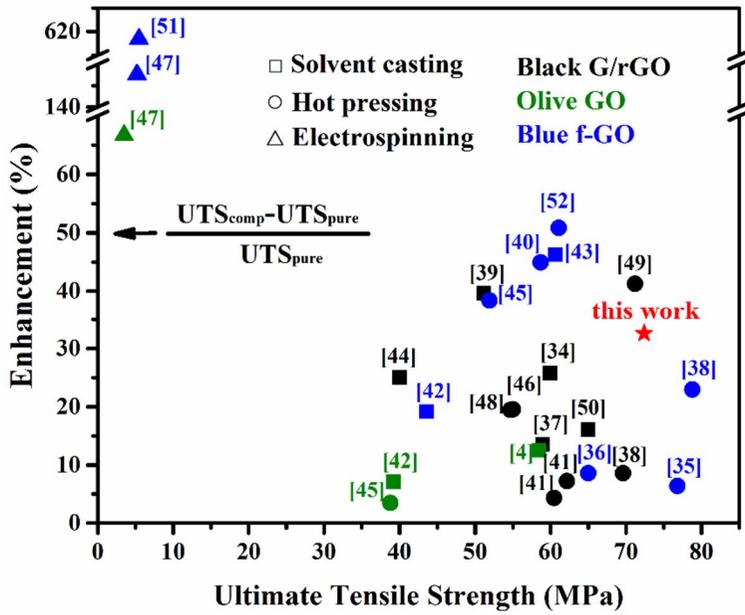

### 3.5 Mechanical Properties of PLA Nanocomposite Membrane

**Fig. 3.15.** the typical stress-strain curves (A) and ultimate tensile strength and Young's modulus (B) of pure PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>/PLA nanocomposite membranes.

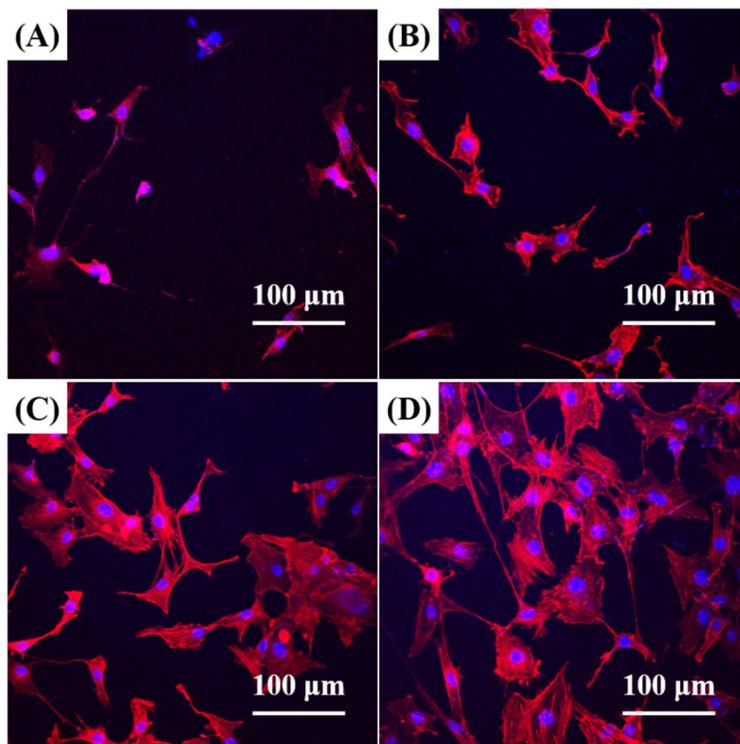

The mechanical properties were evaluated using a tensile test machine equipped with a 1000-N capacity load cell (Instron model 3342, USA) (Fig. 3.15). The ultimate tensile strength (UTS) rose along with the increasing loading content of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>, and descended after reaching at 0.5 wt. %. The optimized UTS was obtained as 72 MPa. The same trend was also observed in the case of Young's modulus, whose optimized value was 2.2 GPa. These results conformed to the analysis of the amount and distribution of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> in the nanocomposite membranes (Fig. 3.14). The mechanical properties of nanocomposite membranes

were reinforced by the homogenously distributed secondary phases, whereas it deteriorated when the filler content saturated due to the aggregation of loaded flakes. This phenomenon was also widespread in the graphene-enhanced nanocomposite materials. <sup>[156]</sup> In addition, we noticed that the optimized UTS in this research was quite high compared with the previous works (**Fig. 3.16**), where the graphene or its derivative was used as the enhanced secondary phase for PLA. Since these works adopted different preparation methods, the direct comparison of absolute UTS could not reflect the merit of our work accurately. Hence, the enhancement of optimized UTS was calculated on basis of the pure PLA membrane which was fabricated using the same method. The enhancement in this work was about 33%. It was almost the highest in contrast with the graphene-enhanced works where the solvent casting was adopted. The reason could be ascribed to the strong interaction between OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and PLA, which ensured the efficient load transferring between these two components.

**Fig. 3.16.** Comparison of UTS and its enhancement of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membrane in this work with those of the membranes which were enhanced by graphene (or reduced GO), GO, and functional group modified GO from the references. <sup>[34-52]</sup>

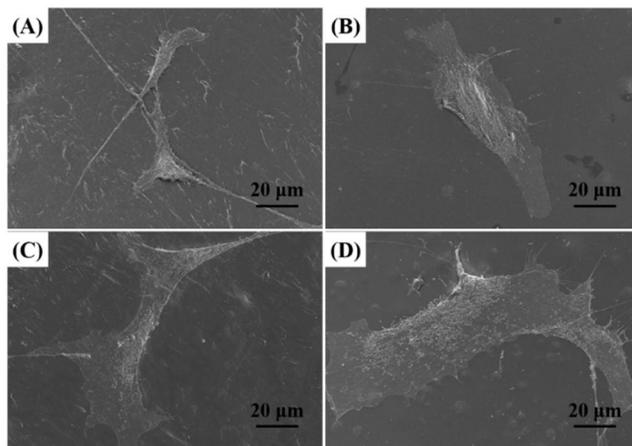

### 3.6 Biocompatibility of PLA Nanocomposite Membrane

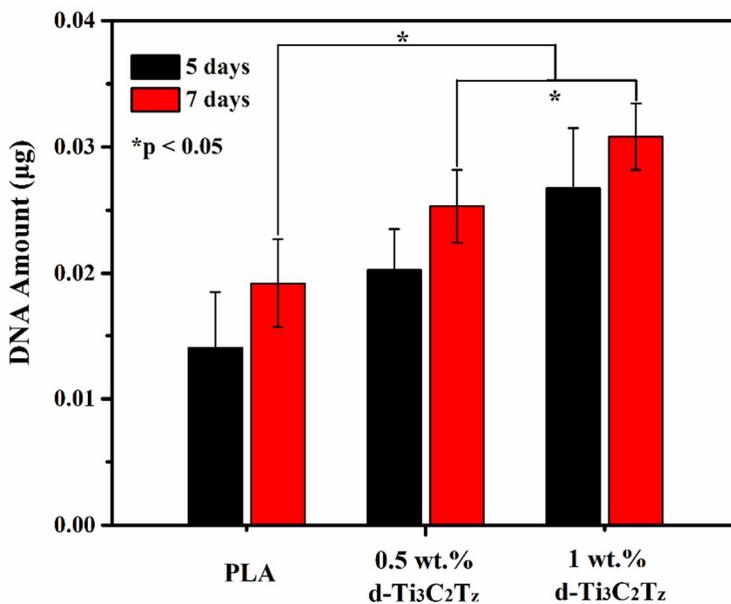

**Fig. 3.17.** Typical CLSM images of adherent MC3T3-E1 cells on pure PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>/PLA nanocomposite membranes: **(A)** Pure PLA, **(B)** 0.2 wt. %, **(C)** 0.5 wt. %, **(D)** 1 wt. %.

The detailed procedure of *in vitro* tests in this section was the same as **Section 3.2.2.1**. In brief, the MC3T3-E1 cells were employed to evaluate the biocompatibility of PLA membranes after enhanced by OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>. After

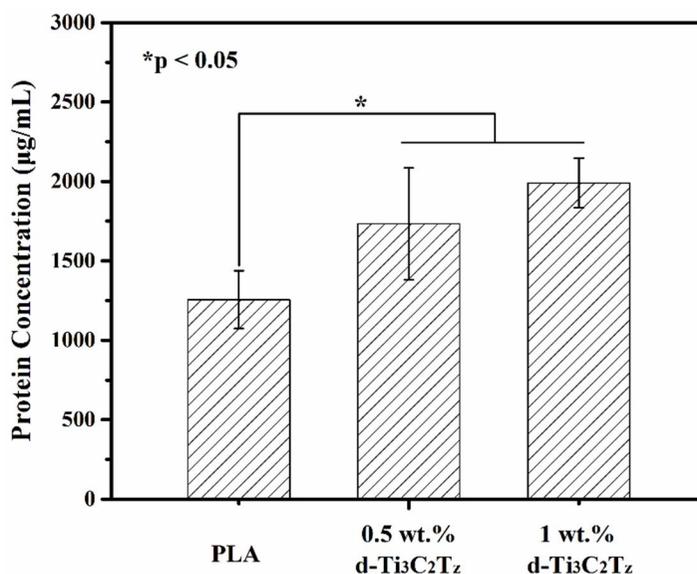

24-hour incubation (Seeding cell density,  $5 \times 10^4$  cells/mL), the CLSM images exhibited that more preosteoblasts attached on the OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membranes (**Fig. 3.17**). Likewise, the cell spreading area of preosteoblasts had an intimate connection with the loading content of d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> in the nanocomposite membranes (**Fig. 3.17**). In addition, the SEM was also used to detect the spreading of preosteoblasts on the PLA membranes, where the adherent cells were fixed with 2.5% glutaraldehyde and dehydrated in graded ethanol. The results were shown in **Fig. 3.18**. The typical SEM images exhibited that the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> promoted the spreading of preosteoblasts on the nanocomposite membranes.

**Fig. 3.18.** Typical SEM images of adherent MC3T3-E1 cells on pure PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membranes: **(A)** Pure PLA, **(B)** 0.2 wt. %, **(C)** 0.5 wt. %, **(D)** 1 wt. %.

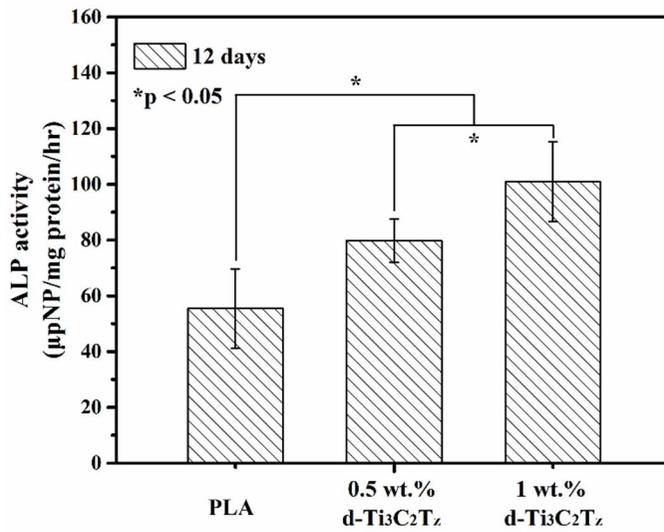

**Fig. 3.19.** DNA assay for determining the cell viability of preosteoblasts on the pure PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> enhanced PLA composite membranes after 5-day and 7-day incubation. Seeding cell density was  $1 \times 10^4$  cells/mL.

**Fig. 3.20.** The amount of protein obtained from the preosteoblasts after incubating on the pure PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> enhanced PLA composite membranes for 12 days. Seeding cell density was  $0.5 \times 10^4$  cells/mL.

The d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was also authenticated to improve the proliferation of preosteoblasts. The cell viability determined by DNA assay showed that preosteoblasts much more actively proliferated on the OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membranes after 7-day incubation (**Fig. 3.19**). Similarly, the larger amount of protein was obtained after the preosteoblasts being incubated on the OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membranes for 12 days (**Fig. 3.20**). Then the analysis of ALP activity indicated that the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> could also promote osteogenic

differentiation of nanocomposite membrane (**Fig. 3.21**). The above phenomena could be ascribed to the good intrinsic biocompatibility of  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets, which was speculated based on the first-principles calculation in the **Chapter 2**. Herein, *in vitro* tests also exhibited that the Teflon filter coated with  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets had much better biological behaviors with preosteoblasts than that coated with graphene oxide (GO) including cell adhesion, proliferation, and differentiation (**Fig. 3.10**). Hence,  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets are believed to possess good intrinsic biocompatibility since GO has been widely confirmed to significantly promote interfacial bio-interactions by experiments and simulations.<sup>[53-55]</sup> Besides, it was noteworthy that although the aggregation of d- $\text{Ti}_3\text{C}_2\text{T}_z$  impaired the mechanical properties of nanocomposite membranes rapidly (**Fig. 3.15**), the aggregated d- $\text{Ti}_3\text{C}_2\text{T}_z$  did not have a serious negative effect on biocompatibility. On the contrary, it still supported the physiological activities of preosteoblasts in our research, where the loading content range of d- $\text{Ti}_3\text{C}_2\text{T}_z$  in the nanocomposite membranes was 0 - 1wt. % (**Fig. 3.17-3.21**)

**Fig. 3.21.** ALP assay for determining the cell differentiation of preosteoblasts on the pure PLA and OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> enhanced PLA composite membranes after 12-day incubation. Seeding cell density was  $0.5 \times 10^4$  cells/mL.

### 3.7 Conclusion

In summary, this chapter demonstrated the biocompatibility of  $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets (d- $\text{Ti}_3\text{C}_2\text{T}_z$ ) in the osteoblastic condition using GO as reference. A robust strategy was developed to prepare the strong and biocompatible d- $\text{Ti}_3\text{C}_2\text{T}_z$  enhanced PLA nanocomposite membranes. The OTES was successfully used to mediate the interface between hydrophilic d- $\text{Ti}_3\text{C}_2\text{T}_z$  and hydrophobic PLA matrix. The optimized UTS was 72 MPa, which was obtained when the loading content of d- $\text{Ti}_3\text{C}_2\text{T}_z$  was 0.5 wt. %. The enhancement was about 33% compared with pure PLA membrane. In addition, the d- $\text{Ti}_3\text{C}_2\text{T}_z$  was certified to accelerate the cell adhesion and proliferation of preosteoblasts, and promote the osteogenic differentiation on the PLA membrane. Hence, these strong and biocompatible nanocomposite membranes have an intriguing future to be applied as guide bone regeneration membrane.

## Chapter. 4 Conclusion and Perspective

This thesis systematically evaluated the biocompatibility of selected MAX phases ( $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$ ) in respect of different A-site and X-site atoms via *in vitro* tests. A general mechanism for the biocompatibility of MAX phases was proposed using the first-principles calculations. Then the good biocompatibility of theoretical-predicted d- $\text{Ti}_3\text{C}_2\text{T}_z$  was ascertained via *in vitro* tests and these nanosheets were used to enhance the mechanical properties and biocompatibility of PLA membrane. The conclusions were list as follows:

**(1)** The  $\text{Ti}_3\text{AlC}_2$ ,  $\text{Ti}_3\text{SiC}_2$ , and  $\text{Ti}_2\text{AlN}$  were determined to be biocompatible with respect to preosteoblasts and fibroblasts in contrast with the commercial Ti–6Al–4V alloy and pure Ti. **(2)** The cell proliferation and differentiation examination under an osteoblastic environment revealed that  $\text{Ti}_2\text{AlN}$  exhibited the optimal performance among these MAX phases. **(3)** The mechanism for this behavior resulted from the strong affinity of  $\text{Ca}^{2+}$  ions onto the  $\text{TiN}_x\text{O}_y$  layer, which indicated the good biocompatibility of  $\text{Ti}_2\text{AlN}$ . **(4)** Compared with GO, preosteoblasts had a better performance of cell adhesion, proliferation, and osteogenic differentiation on the d- $\text{Ti}_3\text{C}_2\text{T}_z$  nanosheets. **(5)** The OTES successfully mediated the interface

between hydrophilic d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> and hydrophobic PLA matrix. The optimized UTS of OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membranes was 72 MPa (at 0.5 wt. %), which increased by 33% compared with pure PLA membrane. **(6)** The d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub> was also authenticated to accelerate the cell adhesion and proliferation of preosteoblasts, and promote the osteogenic differentiation on the nanocomposite membranes.

This work provided a new route for the selection of specific MAX phases for biomedical applications, such as dental and orthopedic fields. Likewise, the MXene had an intriguing future to simultaneously enhance the mechanical properties and biocompatibility of biopolymer, such as the polymer matrix for GBR membrane. Whereas, in consideration of the time and experimental condition, the following problems left and should be investigated in the future:

**(1)** The intensive and comprehensive mechanism on the biocompatibility of MAX phases should be explored, such as the details of cellular recognition of cell–matrix interactions through biomolecules. **(2)** The influence of the functional groups on the biocompatibility of MXenes should be explored thoroughly. **(3)** The *in vivo* tests should be introduced to evaluate the biocompatibility of MAX phases and the OTES-d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>/PLA nanocomposite membranes. **(4)** A mass production method

should be developed to prepare the d-Ti<sub>3</sub>C<sub>2</sub>T<sub>z</sub>, and the cost should be controlled in the acceptable range for the commercial application.

## Resume

**Chen Ke (陈科)**, born on Aug. 1989, Zhejiang province, China.

### Education:

From Sep. 2008 to Jun. 2012, Bachelor's degree in *Materials Sciences and Engineering*, School of Materials Sciences and Engineering, *University of Sciences and Technology Beijing (USTB)*.

From Sep. 2012 to Jun. 2015, Master's degree in *Materials Physics and Chemistry*, *Ningbo Institute of Materials and Technology, Chinese Academy of Sciences (NIMTE, CAS)* and *University of Chinese Academy of Sciences (UCAS)*. (Academic advisor: Prof. *Qing Huang*)

From Sep. 2015 to Feb. 2018 (expected), Ph.D. in *Materials Sciences and Engineering*, Department of Materials Sciences and Engineering, *Seoul National University (SNU)*. (Academic advisor: Prof. *Hyouun-Ee Kim*)

### **Honors and Awards:**

- 2017.03. Korea Rotary Scholarship Foundation - 정석규 Scholarship
- 2016.09. China Scholarship Council (CSC)
- 2015.09. SNU Global Scholarship 1
- 2015.06. Merit Student of UCAS
- 2012.06. Outstanding Graduates of USTB
- 2012.06. Outstanding Diploma Thesis of USTB
- 2010.11. The Second-Class for the People's Scholarship of USTB
- 2010.11. Merit Student of USTB (besides 2009.11)
- 2009.12. The Second Prize for National Physics Competition for Undergraduate
- 2009.10. National Endeavor Scholarship etc.
