#### **Abstract**

Replacing HDDs with NAND flash-based storage devices (SSDs) has been one of the major challenges in modern computing systems especially in regards to better performance and higher mobility. Although the continuous semiconductor process scaling and multi-leveling techniques lower the price of SSDs to the comparable level of HDDs, the decreasing lifetime of NAND flash memory, as a side effect of recent advanced device technologies, is emerging as one of the major barriers to the wide adoption of SSDs in high-performance computing systems.

In this dissertation, system-level lifetime improvement techniques for recent high-density NAND flash memory are proposed. Unlike existing techniques, the proposed techniques resolve the problems of decreasing performance and lifetime of NAND flash memory by exploiting the I/O context of an application to analyze data lifetime patterns or duplicate data contents patterns.

We first present that I/O activities of an application have distinct data lifetime and duplicate data patterns. In order to effectively utilize the context information, we implemented the program context extraction method. With the program context, we can overcome the limitations of existing techniques for improving the garbage collection overhead and limited lifetime of NAND flash memory.

Second, we propose a system-level approach to reduce WAF that exploits the I/O context of an application to increase the data lifetime predic-

tion for the multi-streamed SSDs. The key motivation behind the proposed

technique was that data lifetimes should be estimated at a higher abstraction

level than LBAs, so we employ a write program context as a stream man-

agement unit. Thus, it can effectively separate data with short lifetimes from

data with long lifetimes to improve the efficiency of garbage collection.

Lastly, we propose a selective deduplication that can avoid unneces-

sary deduplication work based on the duplicate data pattern analysis of write

program context. With the help of selective deduplication, we also propose

fine-grained deduplication which improves the likelihood of eliminating re-

dundant data by introducing sub-page chunk. It also resolves technical dif-

ficulties caused by its finer granularity, i.e., increased memory requirement

and read response time.

In order to evaluate the effectiveness of the proposed techniques, we

performed a series of evaluations using both a trace-driven simulator and

emulator with I/O traces which were collected from various real-world sys-

tems. To understand the feasibility of the proposed techniques, we also im-

plemented them in Linux kernel on top of our in-house flash storage proto-

type and then evaluated their effects on the lifetime while running real-world

applications. Our experimental results show that system-level optimization

techniques are more effective over existing optimization techniques.

#### Chapter 1

#### Introduction

#### 1.1 Motivation

NAND flash memory has recently been widely used as a storage device from embedded systems to high end business servers. Flash memory has been widely used for mobile embedded systems due to its many attractive features for mobile storage devices, such as light weight, low power consumption, durability and high performance.

As NAND flash memory technology, however, scales down to 10-nm and below, NAND flash memory performance is also getting worse. Figure 1 shows a tendency to read and write NAND block speeds in different feature sizes. In Figures 1(a) and (b), the x-axis denotes a feature size of NAND chip, and the y-axis represents the latencies of read and write operations, re-

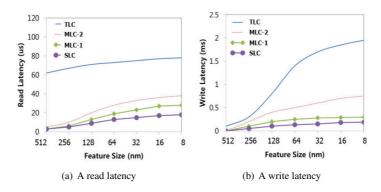

Figure 1: Trends of read and write speeds under various NAND flash chips.

spectively. As shown in Figures 1(a) and (b), both read and write operations are slower as the NAND flash memory density is increased. In the future, as the number of bits per cell is increased and NAND flash memory is scaled down, the performance and data reliability degradation problems is going to be more critical to NAND-based storage systems.

In addition, the limited endurance of NAND flash memory, which has further declined as a side effect of recent advanced device technologies, is becoming a major barrier to the widespread adoption of SSDs. For example, while the NAND capacity per die doubles every two years, the actual lifetime of SSDs does not increase as much as projected because the maximum number of program/erase cycles has decreased [2]. In order for SSDs to be widely adopted, NAND endurance issues should be resolved properly.

#### 1.1.1 Garbage Collection Problem

Due to thehigh-density NAND flash memory performance degradation, the garbage collection (GC) overhead is increased. In NAND flash-based storage systems, garbage collection is necessary when there are not enough free blocks to write new data because NAND flash memory does not allow an inplace update operation. If an update operation is requested, the flash translation layer (FTL) stores the new data in another page. Since the previously written data remained invalid, the FTL triggers GC process in order to reclaim the blocks with the invalidated data so that new data can be stored into NAND flash memory. A GC procedure involves several read, write, and erase operations. Since each operation of NAND flash memory is atomic, the FTL cannot process the next request from the host during an operation

is processed due to the GC process. Because of the performance degradation of write and read operations in high-density NAND flash memory, the response time of each I/O request can be increased when the request is conflicted with a GC process, thus decreasing the application performance. Because this problem can be exacerbated in the future high-density NAND flash memory, an efficient garbage collection algorithm becomes more important.

Many techniques have been proposed to minimize the garbage collection overhead [1]. Regardless the algorithm used for GC, the movement of valid data from selected victim blocks to new blocks takes a significant portion in the total execution time of GC. Therefore, the reduction of the total number of copied data from the victim blocks is a key factor in improving the GC performance. In order to reduce the amount of copied data from the victim blocks, separating data based on their characteristics is a common approach. The number of dead blocks (which have no valid data) or near-dead blocks (which have few valid data) can be increased. The more dead or near-dead blocks are generated, the more likely that they can be selected as victim blocks during GC, thus reducing the overhead of GC.

One of the most commonly used heuristics for data separation is to classify data based on their update frequency. It classifies data based on their write temporal locality, and it treats data with different temporal locality in a different way [3]. This technique assumes that data with high write temporal locality are likely to be updated soon by successive update requests, and therefore the number of dead blocks increases if data with high locality are clustered in the same block. The simplest version of this locality-based data

separator divides data into two groups, hot and cold data depending on the number of updates over a given time period. Hot blocks are more likely to be dead blocks by storing hot data in hot blocks.

#### 1.1.2 Limited Endurance Problem

The limited endurance of NAND flash memory, which has further declined as a side effect of the recent advanced device technologies, is emerging as another major barrier to the wide adoption of SSDs. Since the reduction in the  $MAX_{P/E}$  seriously limits the overall lifetime of flash-based SSDs, the lifetime issues of SSDs should be resolved appropriately for SSDs to be commonly used in enterprise environments.

Since the Lifetime  $L_C$  of an SSD with the total capacity C is proportional to the maximum number  $MAX_{P/E}$  of P/E cycles, and is inversely proportional to the total written data  $W_{day}$  per day,  $L_C$  (in days) can be expressed as follows [4]:

$$L_C = \frac{MAX_{P/E} \times C}{W_{day} \times WAF}$$

, where WAF is a write amplification factor which represents the efficiency of an FTL algorithm. Since  $MAX_{P/E}$  and C is determined when the device is manufactured, we should reduce the WAF and  $W_{day}$  to improve the lifetime of SSDs. Many existing lifetime-improving techniques have been focused on reducing WAF by increasing an FTL algorithm's effectiveness. For example, by avoiding unnecessary data copies during garbage collection using the multi-stream feature, WAF can be reduced. A number of

system-level techniques have been proposed to reduce  $W_{day}$ . For example, write traffic throttling, data compression and data deduplication are such techniques.

However, most existing studies are based on the single I/O layer such as SSD firmware, device driver, and block I/O, so their effectiveness is limited. In order for NAND flash-based storage devices to be widely used in various computing environments, therefore, new approaches to the lifetime problem of recent high-density NAND flash memory are highly required.

#### 1.2 Dissertation Goals

In this dissertation, we propose system-level approaches that improve the performance and lifetime of NAND flash-based storage devices, which overcomes the limitations of the existing techniques. More specifically, our primary goal is to understand high-level information of applications, such as the I/O context of dominant I/O activities, and then develop the lifetime improvement approaches that efficiently exploit such high-level information at various system levels ranging from a system call layer to a flash controller.

First, we propose a system-level approach to reduce WAF that exploits the I/O context of an application to estimate the data lifetime pattern for the multi-streamed SSDs. Thus, it can effectively separate data with short lifetimes from data with long lifetimes to improve the efficiency of garbage collection. Moreover, when data mapped to the same stream show large differences in their lifetimes, long-lived data of the current stream are moved to its internal stream during garbage collection.

Second, we present a write traffic reduction technique to improve the lifetime of SSD by exploiting data similarity of I/O context of an application. We analyze the likelihood of duplicate data for each I/O context and selectively apply deduplication technique to highly duplicated context. By avoiding disturbance of unique context, we can increase the chance of finding duplicate data and decrease the write latency. With the decreased fingerprinting overhead, we propose new deduplication technique to increase the overall deduplication ratio by introducing sub-page chunk.

#### 1.3 Contributions

In this dissertation, we present two system-level techniques to improve the lifetime of NAND flash-based storage devices using program context characteristics. The contributions of this dissertation can be summarized as follows:

- We showed that I/O activities of an application have distinct data lifetime and duplicate data patterns. In order to effectively utilize the context information, we implemented the program context extraction method. With the program context, we can overcome the limitations of existing techniques for improving the garbage collection overhead and limited lifetime of NAND flash memory.
- We propose a fully automatic stream management technique, PC-Stream, which can work efficiently for general I/O workloads with

<sup>&</sup>lt;sup>1</sup>The percentage of identified duplicate writes

heterogeneous write characteristics. PCStream is based on the key insight that stream allocation decisions should be made on dominant I/O activities. By identifying dominant I/O activities using program contexts, PCStream can effectively separate different lifetime data into different streams.

- We propose a selective deduplication using program contexts called PCDedup. We analyze the likelihood of finding duplicate data for each PCs. For low dedup ratio PCs, we skips the deduplication step to avoid unnecessary fingerprinting overhead. We also proposed a fine-grained deduplication technique for flash-based SSDs. With the selective deduplication, PCDedup can increase the likelihood of finding duplicates by using a finer deduplication unit.
- We implement the proposed techniques in the Linux kernel and our in-house flash storage prototype. Then, we evaluate their effects on performance and lifetime using various real-world applications on the real SSD device with firmware modification as well as the emulator.

#### 1.4 Dissertation Structure

This dissertation is composed of five chapters. The first chapter is the introduction of theh dissertation, while the last chapter serves as conclusions with a summary and future work. The three intermediate chapters are organized as follows:

Chapter 2 provides the background for multi-streamed SSDs and data deduplication techniques as well as the overall architecture of NAND flashbased storage devices. We also describe the existing performance and lifetime improvement techniques for flash-based devices, focusing on multistreamed SSDs and deduplication techniques which are highly related to our proposed techniques.

Chapter 3 presents the definition of program contexts and how to extract them. Also, distinct lifetime patterns for PCs and duplicate data patterns are shown.

In Chapter 4, we present a new data separation technique, called PC-Stream, for multi-streamed SSDs. We explain the relationship of dominant I/O activities with data lifetime patterns. By exploiting distinct lifetime patterns of I/O activities, we can achieve high reduction in WAf.

Chapter 5 introduces a selective deduplication technique, called PCD-edup, for NAND flash-based storage devices. We describe the patterns of duplicate data with in a page. Finally, we show how effective the proposed technique is in terms of write traffic reduction.

#### Chapter 2

#### **Background**

#### 2.1 NAND Flash Memory System Software

In order to overcome the physical limitations of NAND flash memory, such as the limited P/E cycles and the *erase-before-write* restriction, a special software layer, called a flash translation layer (FTL), is usually used in NAND flash memory-based storage systems [1]. The FTL emulates a block device on top of NAND flash memory, thus allowing users to use NAND flash memory as if they were using block device such as hard disk drives (HDD). The FTL is responsible for the address mapping, garbage collection, and wear-leveling. The address mapping function maps a logical block address (LBA) from a host system to a physical block address (PBA) in the NAND flash memory. When an update request occurs, the FTL newly allocates a new free page to the request in NAND flash memory. This update process is called out-place update. The location information of the newly assigned page is maintained in the page mapping table, which keeps track of mapping between LBA and PBA. The old versions of newly written data remain invalid in the original location. The wear-leveling procedure induces all blocks in NAND flash memory to be evenly erased, thus preventing frequently erased blocks from being rapidly worn out than other blocks. Finally, in order to maintain free space in NAND flash memory, the FTL must perform a GC process which reclaims the invalid pages in NAND flash memory.

#### 2.2 NAND Flash-Based Storage Devices

In theory, a NAND flash chip with an 8-bit serial bus provides only 40 MB/s for reads and 13 MB/s for writes. This means that the bandwidth of a single flash chip is severely limited. In addition, this performance is further reduced with MLC NAND flash memory. In order to solve the limited performance of a single flash chip, flash-based storages utilize the parallelism of multiple NAND flash chips.

Figure 2 shows a simplified diagram of typical NAND flash-based storage devices, consisting of a host interface logic, several flash memory packages, flash controller, and processor. The FTL running on the processor receives host commands (e.g., reads and writes) via the host interface module from the host system, and then issues several flash I/O commands to the flash controller. The flash controller handles multiple I/O commands at the same

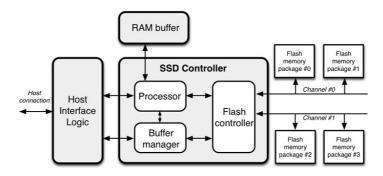

Figure 2: A simplified diagram of typical SSD.

time. Thus, much higher performance can be achieved than using a single NAND flash chip, which provides the aggregate bandwidth of multiple flash chips with the host system.

#### 2.3 Multi-stream Interface

At the heart of the GC problems of SSD are how to predict the lifetime of data written to the SSD and how to ensure that data with similar lifetime are placed in the same erase unit. Kang et al. [20], proposed multi-streaming, an interface that directly manages data placement within the SSD, separating those two issues. Authors argue that the host system should provide appropriate data lifetime to the SSD. It is the responsibility of the SSD, then, to place data with similar lifetime into the same erase unit.

The design introduces the concept of stream. A stream is an abstraction of the allocation of SSD capacity that stores a multiple data with the same lifetime expectancy. An SSD with multi-stream interface allows the host system to open or close streams and write to one of them. Before writing data, the host system opens streams (using special SSD commands) as needed. Both the host system and the SSD share a unique stream ID for each open stream, and the host system adds a proper stream ID to each write. A multi-streamed SSD carefully allocates physical capacity, to place data in a stream together and not to mix data from different streams.

Figure 3 shows the example of the block allocation with and without the multi-stream. Without multi-stream, data are written in the order in which they are received. Consequently, different lifetimes of data are mixed

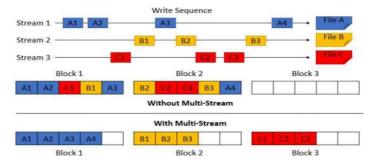

Figure 3: Block allocation with and without multi-stream.

into the same block. Due to the different invalidation time, it incurs high valid page copy overhead for GC. However, with multi-stream, data with same lifetime are separated into a different block so that they are likely to be invalidated together, resulting low GC overhead. In order to maximize the multi-streamed SSD effect, identifying similar lifetime data is the most important and difficult.

Several companies, including Samsung PM953 / PM963, WD Blue 1TB, Toshiba PM5-M SAS SSD and Huawei ES3000 V5, support multistream capability for enterprise SSDs. It seems that Multi-stream is being accepted as part of a general-purpose interface rather than a function provided only by a specific company (T10 SCSI Storage Interface).

#### 2.4 Inline Data Deduplication Technique

Inline deduplication improves the lifetime of SSDs more than offline deduplication [5]. The lifetime of flash cells is limited to a specified small number of P/E cycles (e.g., around 5,000 times in MLC SSD). By writing only unique data blocks, inline deduplication minimizes the number of writes to

the SSDs.

Inline data deduplication generally consists of four steps. First, the deduplication module receives a write request with data  $(Data_a)$  and logical block address  $(LBA_a)$ . Second,  $Data_a$  are divided into fixed-sized chunks or variable-sized chunks. In this dissertation, we use fixed-sized chunking which has a lower CPU utilization requirement and has been commercially used in primary storage [5]. Third, the deduplication module calculates a signature  $(Sig_a)$  for the data  $(Data_a)$ . Fourth, the module searches  $Sig_a$  in the deduplication tables. If the signature matches another signature  $(Sig_b)$  which was already stored, the received write request is considered duplicate  $(Data_a = Data_b)$ . Then  $Data_a$  will not be written to the storage and the deduplication module only updates the deduplication tables. The update includes updating a mapping from  $LBA_a$  to the physical block address  $(PBA_b)$  of the matched signature. In cases where step four cannot find  $Sig_a$  in the table, the write request is considered unique. Therefore, in addition to updating the deduplication tables,  $Data_a$  are written to the storage devices.

#### 2.5 Related Work

# 2.5.1 Data Separation Techniques for Multi-streamed SSDs

There are several research for detecting data temperature. Park, et al. [6] uses multiple bloom filters to identify hot data in the device layer. Stoica, et al. [7] propose new data placement algorithms to improves flash write performance by estimating data update frequencies. Luo, et al. [8] observe high temporal

write locality in different workloads and design a write-hotness aware retention management policy to improve flash memory life time. Most research is based on a simulation or mathematical modeling and lacks the analysis of real world system and performance. It is difficult to guarantee the benefit of these algorithms in a complex I/O intensive datacenter workloads. In adition, as multi-stream SSDs become available, data temperature must be identified and separated to multiple levels (usually more than three levels -hot, cold and warm) to make full use of such devices.

There have been many studies for multi-streamed SSDs [20, 21, 22, 23, 24, 46]. Kang *et al.* first proposed a multi-streamed SSD that supported manual stream allocation for separating different types of data [20]. Yang *et al.* showed that a multi-streamed SSD was effective for separating data of append-only applications like RocksDB [21]. Yong *et al.* presented a virtual stream management technique that allows logical streams, not physical streams, to be allocated by applications. Unlike these studies that involve modifying the source code of target programs, PCStream automates the stream allocation with no manual code modification.

Rho *et al.* proposed a stream management technique, called FStream, at the file system layer [23]. In FStream, metadata, journal data, and user data that may have different lifetime characteristics were allocated to separate streams. Since FStream was implemented as a part of a file system, it was not able to directly detect application's I/O behaviors. Also, it may be hard to be deployed in practice due to a strong dependence on file system-specific implementation details. PCStream, on the other hand, efficiently exploits programs' I/O behaviors using PCs with no file system-specific modifica-

tions.

Yang et al. presented an automatic stream management technique at the block device layer [24]. Similar to hot-cold data separation technique used in FTLs, it approximates the data lifetime of data based on update frequencies of LBAs. The applicability of this technique is, however, quite limited to in-place update workloads only. PCStream has no such limitation on the workload characteristics, thus effectively working for general I/O workloads including append-only, write-once as well as in-place update workloads.

Ha *et al.* proposed an idea of using PCs to separate hot data from cold one in an FTL layer [29]. Kim *et al.* extended it for multi-streamed SSDs [46]. Unlike these work, our study treats the PC-based stream management problem in a more complete fashion by (1) pinpointing the key weaknesses of existing multi-streamed SSD solutions, (2) extending the effectiveness of PCs for more general I/O workloads including write-once patterns, and (3) introducing internal streams as an effective solution for outlier PCs. Furthermore, PCStream exploits the globally unique nature of a PC signature for supporting short-lived applications that runs frequently.

#### 2.5.2 Write Traffic Reduction Techniques

In order to extend the lifetime of flash-based SSDs, data deduplication techniques have been used in recent SSDs because they are effective in reducing the amount of data written to flash memory by preventing duplicate data from being written again [54, 55]. As a result, only non-duplicate data, i.e., unique data, are stored in SSDs effectively decreasing the total amount of data written to SSDs.

Data deduplication techniques, which are originally developed for backup systems, are regarded as one of the promising approaches for extending the storage lifetime because of their ability that reduces the amount of write traffic sent to a storage device. In deduplication techniques, a chunk is used as an unit of identification and elimination of duplicate data. Depending on their chunking strategies, deduplication techniques can be categorized into two types, fixed-size deduplication and variable-size deduplication. Fixed-size deduplication divides an input data stream into fixed-size chunks (e.g., pages) [54, 55]. Then, it decides if each chunk data is duplicate and prevents duplicate chunks from being rewritten to flash memory. Unlike fixed-size deduplication, the chunk size of variable-size deduplication is not fixed. Instead, it decides a cut point between chunks using a content-defined chunking (CDC) algorithm which divides the data stream according to the contents [58, 59].

In general, variable-size deduplication techniques can identify more data as duplicate data than the fixed-size deduplication technique. Since variable-size deduplication adaptively changes the size of chunks by analyzing the contents of input stream, duplicate data are more effectively found regardless of their locations. In spite of its advantages, variable-size deduplication is not commonly used in SSDs because of the following practical limitations.

First, the CDC algorithm often requires relatively high computational power and a large amount of memory space. Thus, variable-size deduplication is not appropriate to be employed at the level of storage devices where computing and memory resources are constrained. Second, the size of re-

maining unique data after deduplication may vary in variable-size deduplication. When writing those data, a complicated scheme for data size management is required to form sub-page data chunks to fit in a flash page size, preventing an internal fragmentation. For those reasons, most existing deduplication techniques for SSDs employ fixed-size deduplication, which is relatively simple and does not require a significant amount of hardware resources.

There are several existing studies for fixed-size deduplication for SSDs. F. Chen [54] proposed CAFTL to enhance the endurance of SSDs with a set of acceleration techniques to reduce runtime overhead. A. Gupta [55] also proposed CA-SSD to improve the reliability of SSDs by exploiting the value locality, which implies that certain data items are likely to be accessed preferentially. In these studies, authors focused on the feasibility of deduplication at SSD level and proved its effectiveness rather than improving deduplication itself.

Recently, several deduplication techniques for flash-based storage are proposed. Z. Chen [56] proposed OrderMergeDedup which orders and merges the deduplication metadata with data writes to realize failure-consistent storage with deduplication. W. Li [57] proposed CacheDedup which integrates deduplication with caching architecture to address limited endurance of flash caching by managing data writes and deduplication metadata together, and proposing duplication-aware cache replacement algorithms. These studies focus on systematic approach such as block layer or flash caching. However, this study improves the effect of deduplication in the device-specific domain, so the approach of this study is quite different.

All of these existing deduplication schemes maintain a limited size dedupt table in memory. Since there is an assumption that existing workloads have very frequent patterns of data, they can achieve high performance if they can be kept in memory. Therefore, we used frequency-based table maintenance policy. However, in the latest workload such as RocksDB, it is confirmed through analysis that the pattern in which the data recorded once is rewritten by the compaction process is more important than the same data repeatedly. Therefore, a new type of table management technique is needed in this workload.

# 2.5.3 Program Context based Optimization Techniques for Operating Systems

Prediction techniques based on history exploit the principle that most programs show certain degrees of repetitive behavior. For instance, subroutines in an application are called multiple times, and loops process a large amount of data. The challenge in making an precise prediction is to link the past event (behavior) to its future reoccurrence. In particular, predictors need the program context of past events so that future events in the same context can be identified. The more accurate context information the predictor has about the past and future events, the more accurate prediction it can make about future program behavior [28].

A key observation in computer architecture is that a particular instruction usually performs a very unique task and rarely changes behavior, so program instructions provide a highly effective way to record the context of program behavior. Since the instructions are described uniquely by their program counters (PCs) that specify the location of the instructions in memory, PCs offer a way to record the program context.

One of the earliest predictors to benefit from the information provided by PCs is branch prediction. The PC of the branch instruction identifies the branch in the program uniquely and is associated with a particular behavior, for instance, to take or not to take the branch. Branch prediction techniques correlate the past behavior of a branch instruction and predict its future behavior when it meets the same instructions.

The success in using the program counter in branch prediction was noted and the PC information was widely used in other predictor designs in computer architecture. Number of PC-based predictors have been proposed to optimize energy [9], cache management [10], and memory prefetching [11]. For instance, PCs were used to accurately predict the instruction behavior in the pipeline of processors which allows the hardware to apply power reduction techniques at the right time to minimize the impact on performance [9]. In Last Touch Predictor [10], PCs are used to predict which data will not be used again by the processor and free the cache to store or prefetch more relevant data. In PC-based prefetch predictors [11], a set of memory addresses or patterns are linked to a particular PC and the next set of data is prefetched when that PC is found again.

In addition, PCC [27] takes into account the opportunity and viability of PC-based prediction techniques in the design of operating systems. In particular, they consider the problem of buffer cache management, which shares common features with hardware cache management, since they deal

essentially with different levels of the memory hierarchy. The basic idea is to separate access streams from the program context (identified by the function call stack) when the I/O access is made, assuming that in the future a single program context will likely to access disk files with the same pattern.

However, none of the existing PC-based approach focus of the storage devices. They use iterative access characteristics according to the PC at the operating system level, e.g., cache management. Based on our analysis on PCs, program context can be a good candidate for optimizing performance and lifetime of SSDs.

#### **Chapter 3**

### **Program Context-based Analysis**

# 3.1 Definition and Extraction of Program Context

In developing an efficient optimization technique for general I/O workloads, our key insight was that in most applications, the overall I/O behavior of applications is decided by a few dominant I/O activities (e.g., logging and flushing in RocksDB). Moreover, data written by dominant I/O activities tend to have distinct I/O patterns. Therefore, if such dominant I/O activities of applications can be automatically detected and distinguished each other in an LBA-oblivious fashion, an optimization technique can be developed for varying I/O workloads including append-only workloads.

In this dissertation, we argue that a program context can be used to build an efficient general-purpose classifier of dominant I/O activities. Here, a PC represents an execution path of an application which invokes write-related system call functions such as write() and writev(). There could be various ways of extracting PCs, but the most common approach [27, 28] is to represent each PC with its PC signature which is computed by summing program counter values of all the functions along the execution path which leads to a write system call.

In RocksDB, dominant I/O activities include logging, flushing and com-

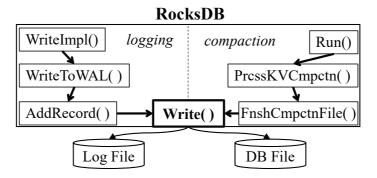

Figure 4: An illustration of (simplified) execution paths of two dominant I/O activities in RocksDB.

paction. Since these I/O activities are invoked through different function-call paths, we can easily identify dominant I/O activities of RocksDB using PCs. For example, Fig. 4 shows (simplified) execution paths for logging and compaction in RocksDB. The sum of program counter values of the execution path WriteImpl()→WriteToWAL()→ AddRecord() is used to represent a PC for the logging activity while that of the execution path Run()→ProcessKeyValueCompaction()→FinishCompactionFile() is used for the compaction activity. In SQLite, there exist two dominant I/O activities which are logging and managing database tables. Similar to the RocksDB, SQLite writes log files and database files using different execution paths. In GCC, there exist many dominant I/O activities of creating various types of temporal files and object files.

As mentioned earlier, a PC signature, which is used as a unique ID of each program context, is defined to be the sum of program counters along the execution path of function calls that finally reaches a write-related system function. In theory, program counter values in the execution path

can be extracted in a relatively straightforward manner. Except for inline functions, every function call involves pushing the address of the next instruction of a caller as a return address to the stack, followed by pushing a frame pointer value. By referring to frame pointers, we can back-track stack frames of a process and selectively get return addresses for generating a PC signature. Fig. 5(a) illustrates a stack of RocksDB corresponding to Fig. 4, where return addresses are pushed before calling write(), AddRecord() and WriteToWAL(). Since frame pointer values in the stack hold the addresses of previous frame pointers, we can easily obtain return addresses and accumulate them to compute a PC signature.

The frame pointer-based approach for computing a PC signature, however, is not always possible because modern C/C++ compilers often do not use a frame pointer for improving the efficiency of register allocation. One example is a -fomit-frame-pointer option of GCC [36]. This option enables to use a frame pointer as a general-purpose register for performance, but makes it difficult for us to back-track return addresses along the call chains.

We employ a simple but effective workaround for back-tracking a call stack when a frame pointer is not available. When a write system call is made, we scan every word in the stack and checks if it belongs to process's code segment. If the scanned stack word holds a value within the address range of the code segment, it assumes that it is a return address. Fig. 5(b) shows the scanning process. Since scanning the entire stack may takes too long, we stop the scanning step once a sufficient number of return address candidates are found. In the current implementation, the scanning process

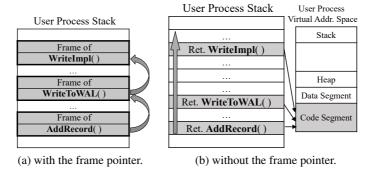

Figure 5: Examples of PC extraction methods.

stops early once five return address candidates are identified. Even though it is quite ad-hoc, this restricted scan is quite effective in distinguishing different PCs because it is very unlikely that two different PCs reach the same write() system call through the same execution subpath that covers five proceeding function calls. In our evaluation on a PC with 3.4 GHz Intel CPU, the overhead of the restricted scan was almost negligible, taking only  $300\sim400~nsec$  per write() system call.

#### 3.2 Data Lifetime Patterns of I/O Activities

In developing automatic stream management technique, our key insight was that in most applications, (regardless of their I/O workload characteristics) a few dominant I/O activities exist and each dominant I/O activity represents the application's important I/O context (e.g., for logging or for flushing). Furthermore, most dominant I/O activities tend to have distinct data lifetime patterns. In order to distinguish data by their lifetimes, therefore, it is important to effectively distinguish dominant I/O activities from each other.

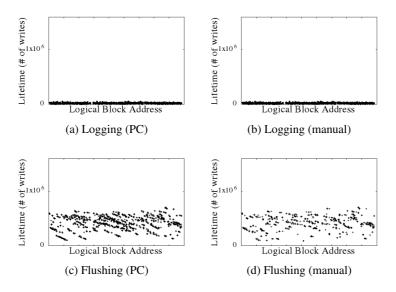

Figure 6: Data lifetime distributions of different PCs.

For example, in update workloads, LBAs alone were effective in separating dominant I/O activities. In this dissertation, we argue that a program context is an efficient general-purpose indicator for separating dominant I/O activities regardless of the type of I/O workloads.

In order to validate our hypothesis that PCs can be useful for estimating lifetimes by distinguishing dominant I/O activities, we conducted experiments using RocksDB, comparing the accuracy of identifying dominant I/O activities using two different methods. First, we manually identified dominant I/O activities by inspecting the source code. Second, we automatically decided dominant I/O activities by extracting PCs for write-related system functions. Fig. 6 illustrates two dominant I/O activities matched between two methods. As shown in Fig. 6(a) and 6(b), the logging activity of RocksDB is correctly identified by two methods. Furthermore, from the

logging-activity PC, we can clearly observe that data written from the PC are short-lived. Similarly, from Fig. 6(c) and 6(d), we observe that data written from the flushing-activity PC behave in a different fashion. For example, data from the flushing-activity PC remain valid a lot longer than those from the logging-activity PC.

# 3.3 Duplicate Data Patterns of I/O Activities

We analyzed the relationship between I/O activities and the duplicate data patterns of several applications such as RocksDB and GCC. Although it was difficult to find an I/O activity which is likely to have duplicate data, we can find the relative difference in duplication rates (i.e., the percentage of duplicate requests in total requests) for I/O activities for two reasons.

First, some activity reads and manipulates data stored in the device and write them, e.g., compaction activity of RocksDB. Compaction activity merges multiple files which incurs reading multiple files from the device and writing them to the device after sorting. If the key range is skewed, we may find untouched data sequence (same sequence as in read file) after sorting. The untouched data are regarded as duplicate data in the device. Unlike compaction activity, the probability of finding duplicate data for logging and flushing activities is not very high because data contents of logging and flushing activities are decided by users. In summary, it is better to focus on compaction rather than logging and flushing to find duplicate data.

Second, activities with short-lived data are hard to be referenced, e.g., temporary files during compiling. Most deduplication techniques work in

the same way when duplicate data is not found. As a regular write, an updated or trimmed page is invalidated. However, the existing deduplication techniques for SSDs does not consider handling a fingerprint of an invalidated page. The fingerprint value in the dedup table should be removed when the invalid page is erased. We assume the fingerprint is removed right after the page invalidation because removing all the fingerprints of invalid pages before erasing a block make GC overhead more severe. Then, fingerprint of short-lived data can not stay long enough to be deduplicated. In summary, we can avoid deduplication for PCs with short-lived data.

In order to validate our analysis, we measured duplicate rate of aforementioned applications. Table 1 shows the duplicate rates of I/O activities for RocksDB and GCC. For RocksDB, Yahoo! Cloud Serving Benchmark (YCSB) [44] with 12-million keys was used to generate update-heavy workloads. For GCC, a Linux kernel was built 30 times. For each build, 1/3 of source files, which were selected randomly, were modified and recompiled. As explained, logging and flushing activities of RocksDB showed very low duplicate rates while compaction activity shows higher duplicate rates. Duplicate rate of outputting temporary file activity is also very low. We can

Application	I/O activity	Duplicate	Total	Duplicate
		requests	requests	rate
RocksDB	logging	0	39181	0%
	flushing	1092	102831	1%
	compaction	32201	398107	8%
GCC	outputting temp files	0	193834	0%
	temp mes			

Table 1: Duplicate rates for I/O activities.

exploit this duplicate data patterns of I/O activities in designing an efficient deduplication technique.

# **Chapter 4**

# Fully Automatic Stream Management For Multi-Streamed SSDs Using Program Contexts

#### 4.1 Overview

In flash-based SSDs, garbage collection (GC) is inevitable because NAND flash memory does not support in-place updates. Since the efficiency of garbage collection significantly affects both the performance and lifetime of SSDs, garbage collection has been extensively investigated so that the garbage collection overhead can be reduced [12, 13, 14, 15, 16, 3]. For example, hot-cold separation techniques are commonly used inside an SSD so that quickly invalidated pages are not mixed with long-lived data in the same block. For more efficient garbage collection, many techniques also exploit host-level I/O access characteristics which can be used as useful hints on the efficient data separation inside the SSD [17, 18].

Multi-streamed SSDs provide a special interface mechanism for a host system, called streams<sup>1</sup>, which data separation decisions *on the host level* can be delivered to SSDs [19, 20]. When the host system assigns two data  $D_1$  and  $D_2$  to different streams  $S_1$  and  $S_2$ , respectively, a multi-streamed

<sup>&</sup>lt;sup>1</sup>In this dissertation, we use "streams" and "external streams" interchangeably.

SSD places  $D_1$  and  $D_2$  in different blocks, which belong to  $S_1$  and  $S_2$ , respectively. When  $D_1$  and  $D_2$  have distinct update patterns, say,  $D_1$  with a short lifetime and  $D_2$  with a long lifetime, allocating  $D_1$  and  $D_2$  to different streams can be helpful in minimizing the copy cost of garbage collection by separating hot data from cold data. Since data separation decisions can be made more intelligently on the host level over on the SSD level, when streams are properly managed, they can significantly improve both the performance and lifetime of flash-based SSDs [20, 21, 22, 23, 24]. We assume that a multi-streamed SSD supports m+1 streams,  $S_0$ , ...,  $S_m$ .

In order to maximize the potential benefit of multi-streamed SSDs in practice, several requirements need to be satisfied both for stream management and for SSD stream implementation. First, stream management should be supported in a fully automatic fashion over general I/O workloads without any manual work. For example, if an application developer should manage stream allocations *manually* for a given SSD, multi-streamed SSDs are difficult to be widely employed in practice. Second, stream management techniques should have no dependency on the number of available streams. If stream allocation decisions have some dependence on the number of available streams, stream allocation should be modified whenever the number of streams in an SSD changes. Third, the number of streams supported in an SSD should be sufficient to work well with multiple concurrent I/O workloads. For example, with 4 streams, it would be difficult to support a large number of I/O-intensive concurrent tasks.

Unfortunately, to the best of our knowledge, no existing solutions for multi-streamed SSDs meet all these requirements. Most existing techniques [20,

21, 22, 23] require programmers to assign streams at the application level with manual code modifications. AutoStream [24] is the only known automatic technique that supports stream management in the kernel level without manual stream allocation. However, since AutoStream predicts data lifetimes using the update frequency of the logical block address (LBA), it does not work well with append-only workloads (such as RocksDB [25] or Cassandra [26]) and write-once workloads (such as a Linux kernel build). Unlike conventional in-place update workloads where data written to the same LBAs often show strong update locality, append-only or write-once workloads make it impossible to predict data lifetimes from LBA characteristics such as the access frequency.

In this dissertation, we propose a *fully-automatic* stream management technique, called PCStream, which works efficiently over general I/O workloads including append-only, write-once as well as in-place update workloads. The key insight behind PCStream is that stream allocation decisions should be made at a higher abstraction level where *I/O activities*, not LBAs, can be meaningfully distinguished. For example, in RocksDB, if we can tell whether the current I/O is a part of a logging activity or a compaction activity, stream allocation decisions can be made a lot more efficiently over when only LBAs of the current I/O is available.

In PCStream, we employ a write program context<sup>2</sup> as such a higher-level classification unit for representing I/O activity regardless of the type of I/O workloads. A program context (PC) [27, 28], which uniquely represents

<sup>&</sup>lt;sup>2</sup>Since we are interested in write-related system calls such as write () in Linux, we use write program contexts and program contexts interchangeable where no confusion arises.

an execution path of a program up to a write system call, is known to be effective in representing dominant I/O activities [29]. Furthermore, most dominant I/O activities tend to show distinct data lifetime characteristics. By identifying dominant I/O activities using program contexts during run time, PCStream can automate the whole process of stream allocation within the kernel with no manual work. In order to seamlessly support various SSDs with different numbers of streams, PCStream groups program contexts with similar data lifetimes depending on the number of supported streams using the k-means clustering algorithm [30]. Since program contexts focus on the semantic aspect of I/O execution as a lifetime classifier, not on the low-level details such as LBAs and access patterns, PCStream easily supports different I/O workloads regardless of whether it is update-only or append-only.

Although many program contexts show that their data lifetimes are narrowly distributed, we observed that this is not necessarily true because of several reasons. For example, when a single program context handles multiple types of data with different lifetimes, data lifetime distributions of such program contexts have rather large variances. In PCStream, when such a program context  $PC_j$  is observed (which was mapped to a stream  $S_k$ ), the long-lived data of  $PC_j$  are moved to a different stream  $S_{k'}$  during GC. The stream  $S_{k'}$  prevents the long-lived data of the stream  $S_k$  from being mixed with future short-lived data of the stream  $S_k$ .

When several program contexts have a large variance in their data lifetimes, the required number of total streams can quickly increase to distinguish data with different lifetimes. In order to effectively increase the number of streams, we propose a new stream type, called an internal stream, which can be used only for garbage collection. Unlike external streams, internal streams can be efficiently implemented at low cost without increasing the SSD resource budget. In the current version of PCStream, we create the same number of internal streams as the external streams, effectively doubling the number of available streams.

In order to evaluate the effectiveness of PCStream, we have implemented PCStream in the Linux kernel (ver. 4.5) and extended a Samsung PM963 SSD to support internal streams. Our experimental results show that PCStream can reduce the GC overhead as much as a manual stream management technique while requiring no code modification. Over AutoStream, PCStream improves the average IOPS by 28% while reducing the average WAF by 49%.

#### 4.2 Motivation

# **4.2.1** No Automatic Stream Management for General I/O Workloads

Most existing stream management techniques [20, 21, 22] require programmers to manually allocate streams for their applications. For example, in both ManualStream<sup>3</sup> [20] and [21], there is no systematic guildeline on how to allocate streams for a given application. The efficiency of stream allocations largely depends on the programmer's understanding and expertise

<sup>&</sup>lt;sup>3</sup>For brevity, we denote the manual stream allocation method used in [20] by Manual-Stream.

on data temperature (*i.e.*, frequency of updates) and internals of database systems. Furthermore, many techniques also assume that the number of streams is known *a priori*. Therefore, when an SSD with a different number of streams is used, these techniques need to re-allocate streams manually. vStream [22] is an exception to this restriction by allocating streams to virtual streams, not external streams. However, even in vStream, virtual stream allocations are left to programmer's decisions.

Although FStream [23] and AutoStream [24] may be considered as automatic stream management techniques, their applicability is quite limited. FStream [23] can be useful for separating file system metadata but it does not work for the user data separation. AutoStream [24] is the only known technique that works in a fully automatic fashion by making stream allocation decisions within the kernel. However, since AutoStream predicts data lifetimes using the access frequency of the same LBA, AutoStream does not work well when no apparent *locality* on LBA accesses exists in applications. For example, in recent data-intensive applications such as RocksDB [25] and Cassandra [26], majority of data are written in an append-only manner, thus no LBA-level locality can be detected inside an SSD.

In order to illustrate a mismatch between an LBA-based data separation technique and append-only workloads, we analyzed the write pattern of RocksDB [25], which is a popular key-value store based on the LSM-tree algorithm [31]. Fig. 7(a) shows how LBAs may be related to data lifetimes in RocksDB. We define the lifetime of data as the interval length (in terms of the logical time based on the number of writes) between when the data is first written and when the data is invalidated by an overwrite or a TRIM

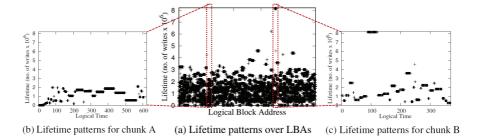

Figure 7: Lifetime distributions of append-only workload over addresses and times.

command [32]. As shown in Fig. 7(a), there is no strong correlation between LBAs and their lifetimes in RocksDB.

We also analyzed if the lifetimes of LBAs change under some predictable patterns over time although the overall lifetime distribution shows large variances. Figs. 7(b) and 7(c) show scatter plots of data lifetimes over the logical time for two specific 1-MB chunks with 256 pages. As shown in Figs. 7(b) and 7(c), for the given chunk, the lifetime of data written to the chunk varies in an unpredictable fashion. For example, at the logical time 10 in Fig. 7(b), the lifetime was 1 but it increases about 2 million around the logical time 450 followed by a rapid drop around the logical time 500. Our workload analysis using RocksDB strongly suggests that under appendonly workloads, LBAs are not useful in predicting data lifetimes reliably. In practice, the applicability of LBA-based data separation techniques is quite limited to a few cases only when the LBA access locality is obvious in I/O activities such as updating metadata files or log files. In order to support general I/O workloads in an automatic fashion, stream management decisions should be based on higher-level information which do not depend on

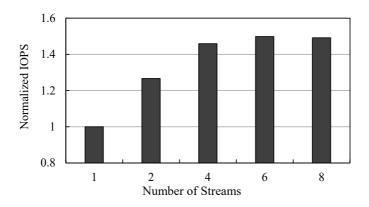

Figure 8: IOPS changes over the number of streams.

lower-level details such as write patterns based on LBAs.

#### 4.2.2 Limited Number of Supported Streams

One of the key performance parameters in multi-streamed SSDs is the number of available streams in SSDs. Since the main function of streams is to separate data with different lifetimes so that they are not mixed in the same block, it is clear that the higher the number of streams, the more efficient the performance of multi-streamed SSDs. For example, Fig. 8 shows how IOPS in RocksDB changes as the number of streams increases on a Samsung PM963 multi-streamed SSD with 9 streams. The db\_bench benchmark was used for measuring IOPS values with streams manually allocated. As shown in Fig. 8, the IOPS is continuously improving until 6 streams are used when dominant I/O activities with different data lifetimes are sufficiently separated. In order to support a large number of streams, both the SBC-4 and NVMe revision 1.3, which define the multi-stream related specifications, allow up to 65,536 streams [19, 33]. However, the number of streams

supported in commercial SSDs is quite limited, say, 4 to 16 [20, 21, 24], because of several implementation constraints on the backup power capacity and fast memory size.

These constraints are directly related to a write buffering mechanism that is commonly used in modern SSDs. In order to improve the write throughput while effectively hiding the size difference between the FTL mapping unit and the flash program unit, host writes are first buffered before they are written to flash pages in a highly parallel fashion for high performance. Buffering host writes temporarily inside SSDs, however, presents a serious data integrity risk for storage systems when a sudden power failure occurs. In order to avoid such critical failures, in data centers or storage servers where multi-streamed SSDs are used, SSDs use tantalum or electrolytic capacitors as a backup power source. When a main power is suddenly failed, the backup power is used to write back the buffered data reliably. Since the capacity of backup power is limited because of the limited PCB size and its cost, the maximum amount of buffered data is also limited. In multi-streamed SSDs where each stream needs its own buffered area, the amount of buffered data increases as the number of streams increases. The practical limit in the capacity of backup power, therefore, dictates the maximum number of streams as well.

The limited size of fast memory, such as TCM [34] or SRAM, is another main hurdle in increasing the number of streams in multi-streamed SSDs. Since multi-stream related metadata which includes data structures for write buffering should be accessed quickly as well as frequently, most SSD controllers implement data structures for supporting streams on fast

memory over more common DRAM. Since the buffered data is the most recent one for a given LBA, each read request needs to check if the read request should be served from the buffered data or not. In order to support a quick checkup of buffered data, probabilistic data structures such as a bloom filter can be used along with other efficient data structures, for accessing LBA addresses of buffered data and for locating buffer starting addresses. Since the latency of a read request depends on how fast these data structures can be accessed, most SSDs place the buffering-related data structure on fast memory. Similarly, in order to quickly store buffered data in flash chips, these data structure should be placed on fast memory as well. However, most SSD manufacturers are quite sensitive in increasing the size of fast memory because it may increase the overall SSD cost. A limited size of fast memory, unfortunately, restricts the number of supported streams quite severely.

## 4.3 Automatic I/O Activity Management

In developing an efficient data lifetime separator for general I/O workloads, our key insight was that in most applications, the overall I/O behavior of applications is decided by a few dominant I/O activities (*e.g.*, logging and flushing in RocksDB). Moreover, data written by dominant I/O activities tend to have distinct lifetime patterns. Therefore, if such dominant I/O activities of applications can be automatically detected and distinguished each other in an LBA-*oblivious* fashion, an automatic stream management technique can be developed for widely varying I/O workloads including append-

only workloads.

In this dissertation, we argue that a program context can be used to build an efficient general-purpose classifier of dominant I/O activities with different data lifetimes. Here, a PC represents an execution path of an application which invokes write-related system call functions such as write() and writev(). There could be various ways of extracting PCs, but the most common approach [27, 28] is to represent each PC with its PC signature which is computed by summing program counter values of all the functions along the execution path which leads to a write system call.

# 4.3.1 PC as a Unit of Lifetime Classification for General I/O Workloads

In order to illustrate that using PCs is an effective way to distinguish I/O activities of an application and their data lifetime patterns, we measured data lifetime distributions of PCs from various applications with different I/O workloads. In this section, we report our evaluation results for three applications with distinct I/O activities: RocksDB [25], SQLite [35], and GCC [36]. RocksDB shows the append-only workload while SQLite shows a workload that updates in place. Both database workloads are expected to have distinct I/O activities for writing log files and data files. GCC represents an extensive compiler workload (*e.g.*, compiling a Linux kernel) that generates many short-lived temporary files (*e.g.*, .s, .d, and .rc files) as well as some long-lived files (*e.g.*, object files and kernel image files).

To confirm our hypothesis that data lifetimes can be distinguished by

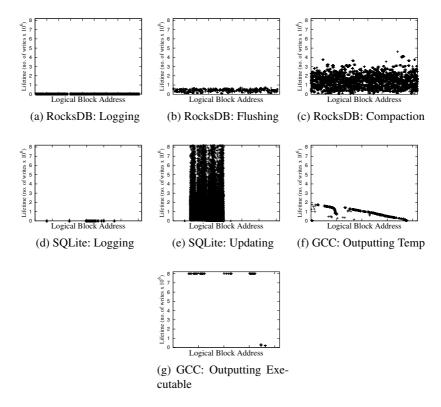

Figure 9: Data lifetime distributions of dominant I/O activities in RocksDB, SQLite and GCC.

tracking dominant I/O activities and a PC is a useful unit of classification for different I/O activities, we have analyzed how well PCs work for RocksDB, SQLite and GCC. Fig. 9 shows data lifetime distributions of dominant I/O activities which were distinguished by computed PC values. As expected, Fig. 9 validates that dominant I/O activities show distinct data lifetime distributions over the logical address space. For example, as shown in Figs. 9(a)~9(c), the logging activity, the flushing activity and the compaction activity in RocksDB clearly exhibit quite different data lifetime distributions. While the logged data written by the logging activity have short

lifetimes, the flushed data by the flushing activity have little bit longer lifetimes. Similarly, for SQLite and GCC, dominant I/O activities show quite distinct data lifetime characteristics as shown in Figs.  $9(d) \sim 9(g)$ . As shown in Fig. 9(d), the logging activity of SQLite generates short-lived data. This is because SQLite overwrites logging data in a small and fixed storage space and then removes them soon. Lifetimes of temporary files generated by GCC are also relatively short as shown in Fig. 9(f), because of the write-once pattern of temporary files. But, unlike the other graphs in Fig. 9, data lifetime distributions of Figs. 9(c) and 9(e), which correspond to the compaction activity of RocksDB and the updating activity of SQLite, respectively, show large variances. These *outlier I/O activities* need a special treatment, which will be described in Section 4.4.

Note that if we used an LBA-based data separator instead of the proposed PC-based scheme, most of data lifetime characteristics shown in Fig. 9 could not have been known. Only the data lifetime distribution of the logging activity of SQLite, as shown in Fig. 9(d), can be accurately captured by the LBA-based data separator. For example, the LBA-based data separator cannot decide that the data lifetime of data produced from the outputting temp activity of GCC is short because temporary files are not overwritten each time they are generated during the compiling step.

### 4.4 Support for Large Number of Streams

The number of streams is restricted to a small number because of the practical limits on the backup power capacity and the size of fast memory. Since the number of supported streams critically impacts the overall performance of multi-streamed SSDs, in this section, we propose a new type of streams, called *internal streams*, which can be supported without affecting the capacity of a backup power as well as the size of fast memory in SSDs. Internal streams, which are restricted to be used only for garbage collection, significantly improve the efficiency of PC-based stream allocation, especially when PCs show large lifetime variances in their data lifetime distributions.

#### 4.4.1 PCs with Large Lifetime Variances

For most PCs, their lifetime distributions tend to have small variances (*e.g.*, Figs. 9(a), 9(d), and 9(f)). However, we observed that it is inevitable to have a few PCs with large lifetime variances because of several practical reasons. For example, when multiple I/O contexts are covered by the same execution path, the corresponding PC may represent several I/O contexts whose data lifetimes are quite different. Such a case occurs, for example, in the compaction job of RocksDB. RocksDB maintains several levels, L1, ..., Ln, in the persistent storage, except for L0 (or a memtable) stored in DRAM. Once one level, say L2, becomes full, all the data in L2 is compacted to a lower level (*i.e.*, L3). It involves moving data from L2 to L3, along with the deletion of the old data in L2. In the LSM tree [31], a higher level is smaller than a lower level (*i.e.*, the size of (L2) < the size of (L3)). Thus, data stored in a higher level is invalidated more frequently than those kept in lower levels, thereby having shorter lifetimes.

Unfortunately, in the current RocksDB implementation, the compaction step is supported by the same execution path (*i.e.*, the same PC) regardless

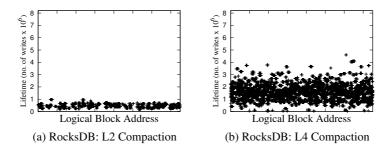

Figure 10: Lifetime distributions of the compaction activity at different levels.

of the level. Therefore, the PC for the compaction activity cannot effectively separate data with short lifetimes from one with long lifetimes. Fig. 10(a) and 10(b) show distinctly different lifetime distributions based on the level of compaction: data written from the level 4 have a large lifetime variance while data written from the level 2 have a small lifetime variance.

Similarly, in SQLite and GCC, program contexts with large lifetime variations are also observed. Fig. 9(e) shows large lifetime variances of data files in SQLite. Since client request patterns will decide how SQLite updates its tables, the lifetime of data from the updating activity of SQLite is distributed with a large variance. Similarly, the lifetime of data from the outputting temporary files of GCC can significantly fluctuate as well depending on when the next compile step starts. Fig. 9(g) shows long lifetimes of object files/executable files after a Linux build was completed (with no more re-compiling jobs). However, the lifetime of the same object files/executable files may become short when if we have to restart the same compile step right after the previous one is finished (e.g., because of code changes).

For these *outlier* PCs with large lifetime variations, it is a challenge to

allocate streams in an efficient fashion unless there are more application-specific hints (*e.g.*, the compaction level in RocksDB) are available. As an ad-hoc (but effective) solution, when a PC shows a large variance in its data lifetime, we allocate an additional stream, called an internal stream, to the PC so that the data written from the PC can be better separated between the original stream and its internal stream. In order to support internal streams, the total number of streams may need to be doubled so that each stream can be associated with its internal stream.

#### **4.4.2** Implementation of Internal Streams

As described in Section 4.2.2, it is difficult to increase the number of (normal) streams. However, if we restrict that internal streams are used only for data movements during GC, they can be quite efficiently implemented without the constraints on the backup power capacity and fast memory size. The key difference in the implementation overhead between normal streams and internal streams comes from a simple observation that data copied during GC do not need the same reliability and performance support as for host writes. Unlike buffered data from host write requests, valid pages in the source block during garbage collection have no risk of losing their data from the sudden power-off conditions because the original valid pages are always available. Therefore, even if the number of internal streams increases, unlike normal streams, no higher-capacity backup capacitor is necessary for managing buffered data for internal streams.

The fast memory requirement is also not directly increased as the number of internal streams increases. Since internal streams are used only for GC

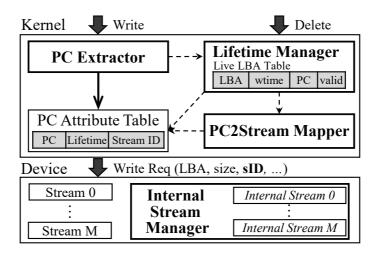

Figure 11: An overall architecture of PCStream.

and most GC can be handled as background tasks, internal streams has a less stringent performance requirement. Therefore, data structures for supporting internal streams can be placed on DRAM without much performance issues. Furthermore, for a read request, there is no need to check if a read request can be served by buffered data as in normal streams because the source block always has the most up-to-date data. This, in turn, allows data structures for internal streams to be located in slow memory. Once an SSD reaches the fully saturated condition where host writes and GC are concurrently performed, the performance of GC may degrade a little because of the slow DRAM used for internal streams. However, in our evaluation, such cases were rarely observed under a reasonable overprovisioning storage capacity.

### 4.5 Design and Implementation of PCStream

In this section, we explain the detailed implementation of PCStream. Fig. 11 shows an overall architecture of PCStream. The PC extractor is implemented as part of a kernel's system call handler as already described in Section 4.3, and is responsible for computing a PC signature from applications. The PC signature is used for deciding the corresponding stream ID<sup>4</sup> from the PC attribute table. PCStream maintains various per-PC attributes in the PC attribute table including PC signatures, expected data lifetimes, and stream IDs. In order to keep the PC attribute table updated over changing workloads, the computed PC signature with its LBA information is also sent to the *lifetime manager*, which estimates expected lifetimes of data belonging to given PCs. Since commercial multi-streamed SSDs only expose a limited number of streams to a host, the *PC2Stream mapper* groups PCs with similar lifetimes using a clustering policy, assigning PCs in the same group to the same stream. Whenever the lifetime manager or the PC2Stream mapper are invoked, the PC attribute table is updated with new outputs from these modules. Finally, the internal stream manager, which was implemented inside an SSD as a firmware, is responsible for handling internal streams associated with external streams.

#### 4.5.1 PC Lifetime Management

The responsibility of the lifetime manager is for estimating the lifetime of data associated with a PC. Except for outlier PCs, most data from the same

<sup>&</sup>lt;sup>4</sup>We call i the stream ID of  $S_i$ .

PC tend to show similar data lifetimes with small variances.

Lifetime estimation: Whenever a new write request R arrives, the lifetime manager stores the write request time, the PC signature,  $PC_i$ , and the LBA list of R into the live LBA table. The live LBA table, indexed by an LBA, is used in computing the lifetime of data stored at a given LBA which belongs to  $PC_i$ . Upon receiving TRIM commands (that delete previously written LBAs) or overwrite requests (that update previously written LBAs), the lifetime manager searches the live LBA table for a PC signature  $PC_{found}$  with the LBA list which includes the deleted/updated LBAs. The new lifetime  $l_{new}$  of  $PC_{found}$  is estimated using the lifetime of the matched LBA from the live LBA table. The weighted average of the existing lifetime  $l_{old}$  for  $PC_{found}$  and  $l_{new}$  is used to update the  $PC_{found}$  entry in the PC attribute table. Note that the written time entry of the live LBA table is updated differently depending on TRIM commands or overwrite requests. The written time entry becomes invalid for TRIM while it is updated by the current time for an overwrite request.

Maintaining the live LBA table, which is indexed by an LBA unit, in DRAM could be a serious burden owing to its huge size. In order to mitigate the DRAM memory requirement, the lifetime manager slightly sacrifices the accuracy of computing LBA lifetime by increasing the granularity of LBA lifetime prediction to 1 MB, instead of 4 KB. The live LBA table is indexed by 1 MB LBA, and each table entry holds PC signatures and written times over a 1 MB LBA range. Because of the coarse-grained indexing, each entry could have multiple signatures and written times, and the same PC could span across multiple entries. If the same PC has different lifetimes, we take

the arithmetic mean as the PC lifetime. To limit the table size, if the table reaches a threshold size, the least recently referenced entry is evicted from the LBA table. Currently, the threshold is set to 64 MB.

PC attribute table: The PC attribute table keeps PC signatures and its expected lifetimes. To quickly retrieve the expected lifetime of a requested PC signature, the PC attribute table is managed through a hash data structure. Each hash entry requires only 12 bytes: 64-bit for a PC signature and 32-bit for a predicted lifetime. The table size is thus small so that it can be entirely loaded in DRAM. From our evaluations, the DRAM size of the PC attribute table was sufficient with several tens or hundreds of KB.

In addition to the main function of the PC attribute table that maintains the data lifetime for a PC, the *memory - resident* PC attribute table has another interesting benefit for the efficient stream management. Since a PC signature of an I/O activity is virtually guaranteed to be *globally unique* across *all* applications (the uniqueness property), and a PC signature does not change over different executions of the same application (the consistency property), the PC attribute table can capture a long-term history of programs' I/O behaviors. Because of the uniqueness and consistency of a PC signature, PCStream can exploit the I/O behavior of even short-lived processes (*e.g.*, cpp and ccl for GCC) that are launched and terminated frequently. When short-lived processes are frequently executed, the PC attribute table can hold their PC attributes from their previous executions, thus enabling quick but accurate stream allocation for short-lived processes.

The consistency property is rather straightforward because each PC signature is determined by the sum of return addresses inside a process's

virtual address space. Unless a program's binary is changed after recompilation, those return addresses remain the same, regardless of program's execution. The uniqueness property is also somewhat obvious from the observation that the probability that distinct I/O activities that take different function-call paths have the same PC signature is extremely low. This is even true for multiple programs. Even though they are executed in the same virtual address space, it is very unlikely that I/O activities of diverged programs taking different function-call paths have the same PC. Consequently, this immutable property of the PC signature for a given I/O activity makes it possible for us to characterize the given I/O activity in a long-term basis without a risk of PC collisions.

#### 4.5.2 Mapping PCs to SSD streams

After estimating expected lifetimes of PC signatures, the PC2Stream mapper attempts to group PCs with similar lifetimes into an SSD stream. This grouping process is necessary because while commercial SSDs only support a limited number of streams (*e.g.*, 9), the number of unique PCs can be larger (*e.g.*, 30). For grouping PCs with similar lifetimes, the PC2Stream mapper module uses the k-means algorithm [30] which is widely used for similar purposes. In PCStream, we use the difference in the data lifetime between two PCs as a clustering distance and generates *m* clusters of PCs for *m* streams. This algorithm is particularly well suited for our purpose because it is lightweight in terms of the CPU cycle and memory requirement. To quickly assign a proper stream to incoming data, we add an extra field to the PC attribute table which keeps a stream ID for each PC signature. More

specifically, when a new write request comes, a designated SSD stream ID is obtained by referring to the PC attribute table using request's PC value as an index. If there is no such a PC in the table, or a PC does not have a designated stream ID, the request gets default stream ID, which is set to 0.

For adapting to changing workloads, re-clustering operations should be performed regularly. This re-clustering process is done in a straightforward manner. The PC2Stream mapper scans up-to-date lifetimes for all PCs in the PC attribute table. Note that PC's lifetimes are updated whenever the lifetime manager gets new lifetimes while handling overwrites or TRIM requests, as explained in Section 4.5.1. With the scanned information, the PC2Stream mapper recomputes stream IDs and updates stream fields of the PC attribute table. In order to minimize unnecessary overhead of frequent reclustering operations, re-clustering is triggered when 10% of the PC lifetime entries in the PC attribute table is changed.

#### 4.5.3 Internal Stream Management

As explained in Section 4.4.1, there are a few outlier PCs with large life-time variances. In order to treat these PCs in an efficient fashion, we devise a two-phase method that decides SSD streams in two levels: the main stream in the host level and its internal stream in the SSD level. Conceptually, long-lived data in the main stream are moved to its internal stream so that (future) short-lived data will not be mixed with long-lived data in the main stream. Although moving data to the internal stream may increase WAF, the overhead can be hidden if we restrict data copies to the internal stream during GC only. Since long-lived data (*i.e.*, valid pages) in a victim

block are moved to a free block during GC, blocks belong to an internal stream tend to contain long-lived data. For instance, PCStream assigns the compaction-activity  $PC_1$  to a main stream  $S_1$  in the first phase. To separate the long-lived data of  $PC_1$  (e.g., L4 data) from future short-lived data of the same  $PC_1$  (e.g., L1 data), valid pages of the  $S_1$  are assigned to its internal stream for the second phase during GC.

We have implemented the internal stream manager with the two-phase method in Samsung's PM963 SSD [38]. To make it support the two-phase method, we have modified its internal FTL so that it manages internal streams while performing GC internally. Since the internal stream manager assigns blocks for an internal stream and reclaims them inside the SSD, no host interface changed is required.

#### 4.5.4 PC Extraction for Indirect Writes

One limitation of using PCs to extract I/O characteristics is that it only works with C/C++ programs that *directly* call write-related system calls. Many programs, however, often invoke write system calls *indirectly* through intermediate layers, which makes it difficult to track program contexts.

The most representative example may be Java programs, such as Cassandra, that run inside a Java Virtual Machine (JVM). Java programs invoke write system calls via the Java Native Interface (JNI) [39] that enables Java programs to call a native I/O library written in C/C++. For Java programs, therefore, the PC extractor shown in Fig. 11 fails to capture Javalevel I/O activities as it is unable to inspect the JVM stack from the native write system call which is indirectly called through the JNI. Another exam-

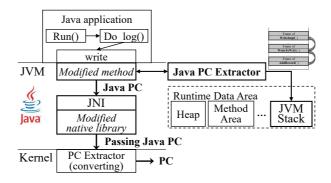

Figure 12: Extracting PCs for JVM.

ple is a program that maintains a write buffer that is dedicated to dealing with all the writes from an application. For example, in MySQL [40] and PostgreSQL [41], every write is first sent to a write buffer. Separate flush threads later materialize buffered data to persistent storage. In that case, the PC extractor only captures PCs of flush threads, not PCs of I/O activities that originally generate I/Os, because the I/O activities were executed in different threads using different execution stacks.

The problem of indirect writes can be addressed by collecting PC signatures at the front-end interface of an intermediate layer that accepts write requests from other parts of the program. In case of Java programs, a native I/O library can be modified to capture write requests and computes their PC signatures. Once a native library is modified, PCStream can automatically gather PC signatures without modifying application programs. Fig. 12 illustrates how PCStream collects PC signatures from Java programs. We have modified the OpenJDK [42] source to extract PC signatures for most of write methods in write related classes, such as OutputStream. The stack area in the Runtime Data Areas of JVM is used to calculate PC

signatures. The calculated PC is then passed to the write system call of the kernel via the modified native I/O libraries.

Unlike Java, there is no a straightforward way to collect PCs from applications with write buffers. This is because the implementation of write buffering is different depending on applications. Additional efforts to manually modify code are unavoidable. However, the scope of this manual modification is limited only to the write buffering code, and application logics themselves don't need to be edited or annotated.

# 4.6 Experimental Results

#### 4.6.1 Experimental Settings

In order to evaluate PCStream, we have implemented it in the Linux kernel (version 4.5) on a PC host with Intel Core i7-2600 8-core processor and 16 GB DRAM. As a multi-streamed SSD, we used Samsung's PM963 480 GB SSDs. The PM963 SSD supports up to 9 streams; 8 user-configurable streams and 1 default stream. When no stream is specified with a write request, the default stream is used. To support internal streams, we have modified the existing PM963 FTL firmware. For a detailed performance analysis, we built a modified nvme-cli [43] tool that can retrieve the internal profiling data from PCStream-enabled SSDs. Using the modified nvme-cli tool, we can monitor WAF values and per-block data lifetimes from the extended PM963 SSD during run time.

We compared PCStream with three existing schemes: Baseline, ManualStream [20], and AutoStream [24]. Baseline indicates a legacy SSD that

does not support multiple streams. ManualStream represents a multi-streamed SSD with manual stream allocation. AutoStream represents the LBA-baed stream management technique proposed in [24].

We have carried out experiments with various benchmark programs which represent distinct write characteristics. RocksDB [25] and Cassandra [26] have append-only write patterns. SQLite [35] has in-place update write patterns and GCC [36] has write-once patterns. For more realistic evaluations, we also used mixed workloads running two different benchmark programs simultaneously.

In both RocksDB and Cassandra experiments, Yahoo! Cloud Serving Benchmark (YCSB) [44] with 12-million keys was used to generate update-heavy workloads (workload type A) which consists of 50/50 reads and writes. Since both RocksDB and Cassandra are based on the appendonly LSM-tree algorithm [31], they have three dominant I/O activities (such as logging, flushing, and compaction). Cassandra is written in Java, so its PC is extracted by the modified procedure described in Section 4.4. In SQLite evaluations, TPC-C [45] was used with 20 warehouses. SQLite has two dominant I/O activities such as logging and updating tables. In GCC experiments, a Linux kernel was built 30 times. For each build, 1/3 of source files, which were selected randomly, were modified and recompiled. Since GCC creates many temporary files (e.g., .s, .d, and .rc) as well as longlived files (e.g., .o) from different compiler tools, there are more than 20 dominant PCs. To generate mixed workloads, we run RocksDB and GCC scenarios together (denoted by Mixed 1), and run SQLite and GCC scenarios at the same time (denoted by Mixed 2). In order to emulate an aged SSD

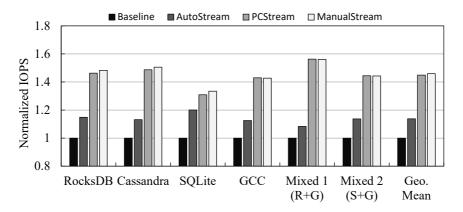

Figure 13: A comparison of normalized IOPS.

in our experiments, 90% of the total SSD capacity was initially filled up with user files before benchmarks run.

#### 4.6.2 Performance Evaluation

We compared IOPS values of three existing techniques with PCStream. Fig. 13 shows normalized IOPS for six benchmarks with four different techniques. For all the measured IOPS values<sup>5</sup>, PCStream improved the average IOPS by 45% and 28% over Baseline and AutoStream, respectively. PCStream outperformed AutoStream by up to 56% for complex workloads (*i.e.*, GCC, Mixed1 and Mixed 2) where the number of extracted PCs far exceeds the number of supported streams in PM963. The high efficiency of PCStream under complex workloads comes from two novel features of PCStream: (1) LBA-oblivious PC-centric data separation and (2) a large num-

<sup>&</sup>lt;sup>5</sup>For RocksDB, Cassandra, and SQLite, the YCSB benchmark and TPC-C benchmark compute IOPS values as a part of the benchmark report. For GCC, where an IOPS value is not measured during run time, we computed the IOPS value as a ratio between the total number of write requests (measured at the block device layer) and the total elapsed time of running GCC.

ber of streams supported using internal streams. AutoStream, on the other hands, works poorly except for SQLite where the LBA-based separation can be effective. Even in SQLite, PCStream outperformed AutoStream by 10%.

#### 4.6.3 WAF Comparison

Fig. 14 shows WAF values of four techniques for six benchmarks. Overall, PCStream was as efficient as ManualStream; Across all the benchmarks, PCStream showed similar WAF values as ManualStream. PCStream reduced the average WAF by 63% and 49% over Baseline and AutoStream, respectively.

As expected, Baseline showed the worst performance among all the techniques. Owing to the intrinsic limitation of LBA-based data separation, AutoStream performs poorly except for SQLite. Since PCStream (and ManualStream) did not depend upon LBAs for stream separations, they performed well consistently, regardless of write access patterns. As a result, PCStream reduced WAF by up to 69% over AutoStream.

One interesting observations in Fig. 14 is that PCStream achieved a lower WAF value than even ManualStream for GCC, Mixed 1, and Mixed 2 where more than the maximum number of streams in PM963 are needed. In ManualStream, DB applications and GCC were manually annotated at offline, so that write system calls were statically bound to specific streams during compile time. When multiple programs run together as in three complex workloads (*i.e.*, GCC, Mixed 1 and Mixed 2), static stream allocations are difficult to work efficiently because they cannot adjust to dynamically changing execution environments. However, unlike ManualStream,

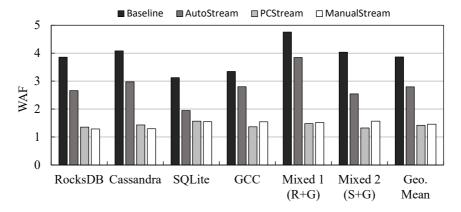

Figure 14: A comparison of WAF under different schemes.

PCStream continuously adapts its stream allocations during run time, thus quickly responding to varying execution environments.

#### 4.6.4 Per-stream Lifetime Distribution Analysis

To better understand the benefit of PCStream on the WAF reduction, we measured per-stream lifetime distributions for the Mixed 1 scenario. Fig. 15 shows a box plot of data lifetimes from the 25th to the 75th percentile. As shown in Fig. 15, streams in both PCStream and ManualStream are roughly categorized as two groups,  $G1 = \{S_1, S_2, S_3, S_4, S_5\}$  and  $G2 = \{S_6, S_7, S_8\}$ , where G1 includes streams with short lifetimes and small variances (i.e.,  $S_1, S_2, S_3, S_4$ , and  $S_5$ ) and G2 includes streams with large lifetimes and large variances (i.e.,  $S_6, S_7, S_8$ ). The  $S_0$  does not belong to any groups as it is assigned to requests whose lifetimes are unknown. Even though the variance in the  $S_0$  is wider than that in ManualStream, PC-Stream showed similar per-stream distributions as ManualStream. In par-

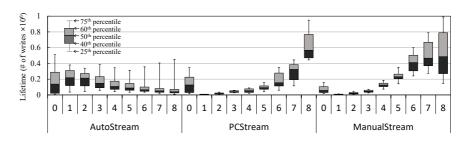

Figure 15: A Comparison of per-stream lifetime distributions.

ticular, for the streams in G2, PCStream exhibited smaller variance than ManualStream, which means that PCStream separates cold data from hot data more efficiently. Since PCStream moves long-lived data of a stream to its internal stream, the variance of streams with large lifetimes tend to be smaller over ManualStream.

AutoStream was not able to achieve small per-stream variances as shown in Fig. 15 over PCStream and ManualStream. As shown in Fig. 15, all the streams have large variances in AutoStream because hot data are often mixed with cold data in the same stream. Since the LBA-based data separation technique of AutoStream does not work well with both RocksDB and GCC, all the streams include hot data as well as cold data, thus resulting in large lifetime variances.

#### 4.6.5 Impact of Internal Streams

In order to understand the impact of internal streams on different stream management techniques, we compared the two versions of each technique, one with internal streams and the other without internal streams. Since internal streams are used only for GC, they can be combined with any existing

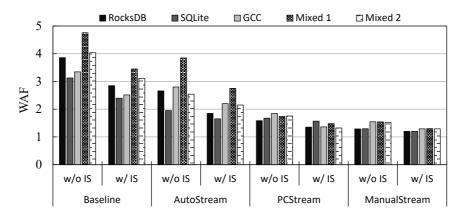

Figure 16: The effect of internal streams on WAF.

stream management techniques. Fig. 16 shows WAF values for five benchmarks with four techniques. Overall, internal streams worked efficiently across the four techniques evaluated. When combined with internal streams, Baseline, AutoStream, PCStream and ManualStream reduced the average WAF by 25%, 22%, 17%, and 12%, respectively. Since the quality of initial stream allocations in Baseline and AutoStream was relatively poor, their WAF improvement ratios with internal streams were higher over PCStream and ManualStream. Although internal streams were effective in separating short-lived data from long-lived data in both Baseline and AutoStream, the improvement from internal streams in these techniques are not sufficient to outperform PCStream and ManualStream. Poor initial stream allocations, which keep putting both hot and cold data to the same stream, unfortunately, offset a large portion of benefits from internal streams.

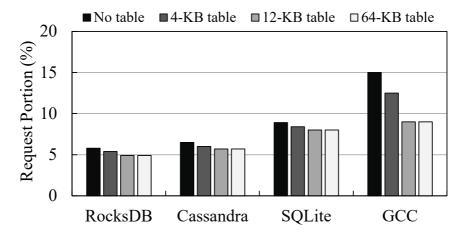

Figure 17: The effect of the PC attribute table.

#### 4.6.6 Impact of the PC Attribute Table

As explained in Section 4.5.1, the PC attribute table is useful to maintain a long-term history of applications' I/O behavior by exploiting the uniqueness of a PC signature across different applications. To evaluate the effect of the PC attribute table on the efficiency of PCStream, we modified the implementation of the PC attribute table so that the PC attribute table can be selectively disabled on demands when a process terminates its execution. For example, in the kernel compilation scenario with GCC, the PC attribute table becomes empty after each kernel build is completed. That is, the next kernel build will start with no existing PC to stream mappings.

Fig. 17 show how many requests are assigned to the default  $S_0$  stream over varying sizes of the PC attribute table. Since  $S_0$  is used when no stream is assigned for an incoming write request, the higher the ratio of requests assigned to  $S_0$ , the less effective the PC attribute table. As shown in Fig. 17,

in RocksDB, Cassandra, and SQLite, the PC attribute table did not affect much the ratio of writes on  $S_0$ . This is because these programs run continuously for a long time while performing the same dominant activities repeatedly. Therefore, although the PC attribute table is not maintained, they can quickly reconstruct it. On the other hand, the PC attribute table was effective for GCC, which frequently creates and terminates multiple processes (*e.g.*, cc1). When no PC attribute table was used, about 16% of write requests were assigned to  $S_0$ . With the 4-KB PC attribute table, this ratio was reduced to 12%. With the 12-KB PC attribute table, only 9% of write requests were assigned to  $S_0$ . This reduction in the  $S_0$  allocation ratio reduced the WAF value from 1.96 to 1.54.

### Chapter 5

# **Deduplication Technique using Program Contexts**

#### 5.1 Overview

As analyzed in Section 3.3, data duplicate patterns and I/O activities seems to have relationship. Particularly, some writes are known a priori to be likely to be unique. Applications might generate data that should not or cannot be deduplicated. For example, some applications write random, compressed, or encrypted data; others write complex formats (e.g., virtual disk images) with internal metadata that tends to be unique.

Attempting to deduplicate unique writes wastes CPU time on hash computation and I/O bandwidth on maintaining the hash index. Unique hashes also increase the index size, requiring more RAM space and bandwidth for look up, insertion, and garbage collection.

In summary, if program context can help to know when it is unwise to deduplicate a write, we can optimize its performance and reliability. We implemented a selective deduplication based on the program context.

Since deduplication uses computational resources and may increase latency, it should only be performed when there is a potential benefit. The program context hint instructs the device not to deduplicate a particular writes.

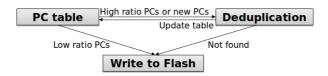

Figure 18: Diagram of selective deduplication.

It has two use cases: (1) unique data: there is no point in wasting resources on deduplicating data that is unlikely to have duplicates, such as short-lived data; (2) reliability: maintaining multiple copies of certain writes may be necessary, e.g., super block replicas in many file systems.

Figure 18 shows a diagram of the proposed selective deduplication technique. When a write request comes, it first query its PC value to the PC table which holds duplicate rate per PCs. If the PC has high duplicate ratio or a new one, we apply deduplication on the request. After fingerprinting and searching, the result is updated to the PC table. If the PC has low duplicate ratio or there is no written data for a new PC, we handle data as a normal request.

## **5.2** Selective Deduplication using Program Contexts

## 5.2.1 PCDedup: Improving SSD Deduplication Efficiency using Selective Hash Cache Management

To see what data has been written, the hash value of the data has to be kept in a memory called dedup table. However, due to the limitation of device internal memory size, some hash values can be retained. So if you fill a

,	(0xA)
Fingerprint	count
0xA	1
0xB	0
0xC	0
0xD	0

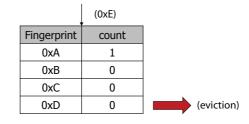

Figure 19: Dedup table management in page-based deduplication.

table of limited size with data that will not be duplicated, the deduplication rate will be lower.

In general, data redundancy is determined by the user, but certain PCs are characterized by high or low probability of duplicate data. For example, RocksDB log data can not overlap with other sst file data because the data structure of the data structure is different, and PCs such as the cp command or gcc executable generation are more likely to generate redundant data. Therefore, if dedup table is managed in consideration of this, efficient deduplication can be achieved.

As shown in Fig. 19, the existing page-based dedup maintains the dedup table in the unit of page. Only the contents of the page (e.g., 0xA in the figure) is compared if they are already written before. If there are duplicate page in the device, the dedup technique just increase its count number and update corresponding mapping table instead of writing them.

Existing frequency based dedup table management increases count when any duplicate fingerprint is found. If all the tables are filled, the entry with the lowest count value is evicted. In Fig. 19, The disadvantage of this approach is that if there is a significant number of data with a low deduplica-

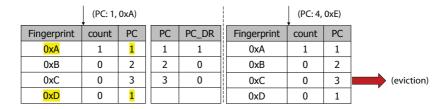

Figure 20: Dedup table management in PC-based deduplication.

tion rate, then a relatively high number of redundant data can be exported. In this study, by managing the PC information and the number of duplicate data occurrences in the dedup table, it is possible to increase the possibility of finding duplicate data by leaving the data of the PC with high possibility of duplicate data in the table.

Fig. 20 shows the difference between the existing page-based deduplication technique and the PC-based deduplication technique. When a new fingerprint occurs, PC deduplication has a policy of preferentially evicting entries that are likely to not duplicate data by selecting the PC with the lowest count as the victim and exporting the entry of that PC.

We propose a PC-based selective deduplication technique to prevent PCs with badly duplicated data from occupying the space of the dedup table. In the previous example, PCs that do not have any more entries in the table, such as PC 3, are not likely to create duplicate data in the future, so add the PC to the blacklist to avoid future deduplication.

The dedup table can be degraded due to unnecessary data. For a PC with a pattern that does not generate redundant data, it does not achieve a significant data reduction even if it takes up space in the dedup table. Rather, they occupy limited memory space and take the opportunity to keep

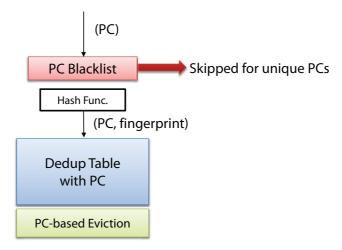

Figure 21: The selective deduplication based on PCs.

redundant data in the table. Therefore, in order to efficiently use the table space, PCDedup determines the degree of data redundancy according to the PC for a certain period of time. PCs that do not have data in the dedup table are added to the PC Blacklist. PCs included in blacklist do not waste dedup table space because they do not perform dedup operation. Fig. 21 shows the overall procedure of PCDedup which selectively conduct the deduplication technique.

We implemented it in the emulator described in the previous example and experimented through various workloads. The baseline is a state in which deduplication is not applied. Sampling is a technique for determining whether to pre-liminarily check any data and deduplicating the remaining data, dedup is a method for deduplication of all data, and PC\_Dedup is a PC-based selective deduplication technique. As shown in the figure, the effects of PC\_Dedup on development and PC usage are well known. Development

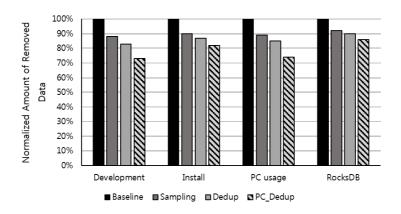

Figure 22: The comparison of the amount of removed data for PC\_Dedup.

is a workload where several users perform kernel compile and source code copy. PC usage performs various document modification and internet use operations. At this time, there are many PCs that produce redundant data and a lot of writing. PCs that can not be clearly distinguished, the PC-based selective technique was effective. On the other hand, in RocksDB, it was hard to see a significant effect because only the case where the same key-value pair is written down to the lower level is through the compaction. The maximum number of expected deduplications in one entry of the dedup table does not exceed the height of the LSM-tree (usually set to 5 to 6). Therefore, to increase the number of possible deduplications, we conducted to remove redundant data in the log file.

RocksDB's log data contains key / value values so we can theoretically expect data redundancy in an SST file. However, the implementation can not recognize the same data because the data layout of the log file differs from that of the SST file. So we modified RocksDB to make the format of

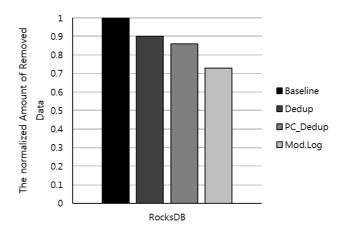

Figure 23: The comparison of the amount of removed data for Mod.Log.

handling key / value in log file the same as SST file. (Mod.Log in the graph below)

Log data can also be deduplicated, reducing log to flush to L1 compaction total 3 writes by one, thus reducing the total write amount by 28%. However, the width to be removed is not so large. As a result of the analysis, we found that the management method of the dedup table based on the frequency creates the inefficiency.

#### **5.2.2 2-level LRU Eviction Policy**

Due to the nature of the LSM-tree workload in which one key / value is repeatedly written many times (unless it is updated), entries that occupy the table in the early stages are rapidly increased in frequency. Since the existing eviction policy only outputs entries with low frequency, entries with increasing frequency will continue to occupy the table. However, the maximum number of deduplications that can be expected for this entry is 5 to 6 times,

Figure 24: The 2-level LRU algorithm.

and the lower the level, the less likely it is to participate in compaction. Even if the key is updated, duplicate data can no longer be removed. That is, key / value already deduplicated has a low expected removal amount, so if you evict them, you can deduplicate a new key / value with a high probability. Therefore, we used 2-level LRU technique which can eviction by considering both frequency and recency.

Fig. 24 shows the 2-level LRU algorithm with each purpose. The data of unique PCs are allocated to the 1st level LRU queue. If duplicate data occurs before they are evicted from the table, the data is moved to the 2nd LRU queue. Unlike the existing technique where duplicate data is not evicted from the table, the 2 level LRU reflects the characteristics of the workload where additional duplication opportunities are limited by giving duplicate data the chance to be kicked out. Since it is important to find additional deduplication opportunities while data is still in the table, instead of simply moving duplicate data to the head of the queue, we move duplicate data to the second level to give an opportunity to remain in the table longer.

Mod.Log\_2L shows the result of applying 2-level LRU. Both PC\_Dedup and Mod.Log have increased the utilization of the table, thus reducing the amount of writing. The reason why Mod.Log\_2L does not write more is be-

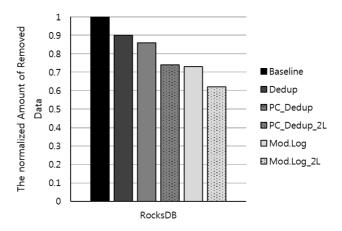

Figure 25: The comparison of the amount of removed data 2-level LRU.

cause the limited memory size did not remove the data going down to the lower level through compaction.

### **5.3** Exploiting Small Chunk Size

#### **5.3.1** Fine-Grained Deduplication

The write-requested page is identified whether the contents of the page have already been written and is written to flash memory only if there is no existing duplicate page. When a write-requested page is the exact duplicate of a previously written page, the requested page is not written to flash memory; only the corresponding entry for a mapping table (between the logical address and physical address) is updated. On the other hand, if there is no existing page duplicate in flash memory whose contents are the same as those of requested one, the requested page has to be written to flash memory. However, even for these unique pages, if their redundancy is checked

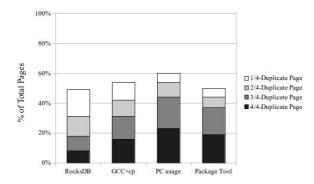

Figure 26: The percentage of pages according to their partial duplicate patterns.

at a sub-page level, say at a quarter of the page size, many sub-pages of these unique pages can be identified as redundant data. In existing techniques based on page-level deduplication, therefore, many duplicate data are written to flash memory even though the same data chunks have already been written.

In order to better understand the effect of fine-grained deduplication on the amount of identified duplicate data, we analyzed how many more chunks can be identified as redundant when the chunk size gets smaller than a single page. For our evaluation, we used four I/O traces, RocksDB, GCC+cp, PC usage, and Package Tool which are explained in Section 5.3.4. In our evaluation, the page size was 4 KB and the chunk size was set to 1 KB.

Fig. 26 shows the percentage of the page writes from host, classified by their partial duplicate patterns. We denote that a page is a n/4-duplicate page when n chunks of the page are duplicate chunks. A 4/4-duplicate page is a duplicate page at the page level. In the existing page-based deduplication, only 4/4-duplicate pages can be identified as a duplicate page. As shown in

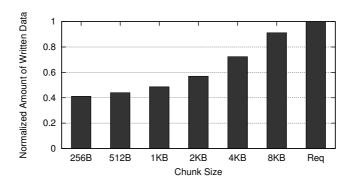

Figure 27: The amount of written data under varying chunk sizes in PC workload.

Fig. 26, 4/4-duplicate pages account for only 8% - 28% of total requested pages. For partially duplicate pages, i.e., 1/4-, 2/4- and 3/4-duplicate pages, the page-based deduplication technique is useless. As shown in Fig. 26, pages with 1-3 duplicate chunks account for 14% - 34%. This means that many duplicate data are unnecessarily written to flash memory due to the large chunk size.

We also investigated the amount of data that can be eliminated by data deduplication while varying the chunk size from 256 B to 8 KB. As shown in Fig. 27, when the chunk size is 1 KB, the amount of data written to flash memory is reduced by 33% over when the chunk size is 4 KB. In particular, when the size of a chunk is 8 KB (i.e., when the physical page size is assumed to be 8 KB), only 10% of requested data are eliminated by data deduplication. This effectively shows that, as the size of a page increases, the overall deduplication ratio, i.e., the percentage of identified duplicate writes, decreases significantly. Since the physical page size of NAND flash memory is expected to increase as the semiconductor process is scaled down [49, 50],

it is expected that the deduplication ratio of the existing deduplication technique will be significantly decreased in near future. In order to resolve this problem, the deduplication chunk size of deduplication techniques needs to be smaller than a page size. As depicted in Fig. 27, the deduplication ratio is saturated when the chunk size is 1 KB. Thus, we use it as a default chunk size in the rest of this dissertation.

In order to effectively incorporate fine-grained deduplication into flash-based SSDs, two key technical issues must be addressed properly. First, fine-grained deduplication requires a larger memory space than a coarse-grained one because it needs to keep more metadata in memory to find small-size duplicate data. Second, in fine-grained deduplication, unique data segments from partially duplicated pages can be scattered across several physical pages, which may seriously degrade the overall read performance. The proposed FineDedup technique is designed to take full advantage of fine-grained deduplication with small memory overhead as well as a low read performance penalty.

In this section, we describe our proposed FineDedup technique in detail. We first explain the overall architecture of FineDedup and describe how FineDedup handles read and write requests. Then we introduce a read performance penalty and memory overheads caused by FineDedup, respectively, and explain how these problems can be resolved in FineDedup.

Fig. 28 shows an overall architecture of FineDedup with its main components. Upon the arrival of a write request, FineDedup stores requested data temporarily in an on-device buffer, which is managed by an LRU algorithm. When the requested data are evicted from the buffer, FineDedup

divides the data into several chunks. (Note that the chunk size is 1 KB in this work, but a different size of chunks can be used as well in FineDedup.)

For each chunk, FineDedup computes a fingerprint, using a collision-resistant hash function. In this work, we use an MD6 hash function [52], which is one of the well-known cryptographic hash functions. A fingerprint is used as a unique ID that represents the contents of a chunk. FineDedup has to compute more fingerprints than the existing deduplication schemes because of its small chunk size. To reduce the hash calculation time, FineDedup uses multiple hardware-assisted hash engines for parallel hash calculations. In our FPGA (ML605) implementation of the MD6 hash function, it took about  $10~\mu s$  to compute a fingerprint using a hardware accelerator. Considering a long write latency (e.g., 1.2~ms) of NAND flash memory, the time overhead of computing fingerprints can be considered negligible.

After fingerprinting, each fingerprint is looked up in the dedup table which maintains the fingerprints of the unique chunks previously written to flash memory. Each entry of the dedup table is composed of a key-value pair, {fingerprint, location}, where the location indicates a physical address in which the unique chunk is stored. If the same fingerprint is found, it is not necessary to write the chunk data because the same chunk is already stored in flash memory. Instead, FineDedup updates the mapping table so that the corresponding mapping entry points to the unique chunk previously written. Unlike existing page-based deduplication techniques, FineDedup handles all the data in the unit of a chunk. For this reason, FineDedup must maintain a chunk-level mapping table that maps a logical chunk address to a physical chunk in flash memory. Because of its finer mapping granularity,

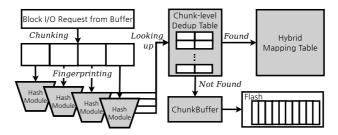

Figure 28: An overview of the proposed FineDedup technique.

the chunk-level mapping table is much larger than the existing page-level mapping table. To reduce the memory space for maintaining the chunk-level mapping table, FineDedup uses a hybrid mapping strategy, which is described in Section 5.3.3 in detail.

If there is no matched fingerprint in the dedup table, FineDedup stores the chunk data in a *chunk buffer* temporarily. This temporary buffering is necessary because the unit of I/O operations of flash memory is a single page. The chunk buffer stores the incoming chunk data until there are four chunks, and evicts them to flash memory at once. FineDedup then updates the mapping table so that the corresponding mapping entries indicate newly written chunks. The new fingerprints of the evicted chunks are finally inserted into the dedup table with their physical location.

When a read request arrives, FineDedup reads all the chunks that belong to the requested page from flash memory, and then transfers the read data to the host system. The physical addresses of the chunks can be obtained by consulting to the mapping table. In FineDedup, four chunks in the same logical page can be scattered across different physical pages. In that case, multiple read operations are required to form the original page data,

which in turn significantly increases the overall read response time. We explain how FineDedup resolves this problem in the following subsection.

#### 5.3.2 Read Overhead Management

FineDedup effectively reduces the number of pages written to flash memory by using a small-size chunk for deduplication, but it incurs two types of additional overheads, i.e., a read performance overhead and a memory space overhead, which are not observed in the existing deduplication techniques. In this subsection, we first introduce why the read performance overhead occurs in FineDedup, and then explain how FineDedup resolves this problem. In the following subsection, we describe our memory space overhead reduction technique in detail.

The main cause of the read performance degradation is data fragmentation which occurs when data chunks belonging to the same logical page are broken up into several physical pages. Fig. 29 illustrates why data fragmentation occurs in FineDedup. There are two page write requests, *Req 1* and *Req 2*, in Fig. 29. *Req 1* consists of four chunks, 'A', 'B', 'C', and 'D', and 'B' of *Req 1* are duplicate chunks, only 'C' and 'D' need to be written to flash memory. Suppose that there is a read request for the page data written by *Req 1*. In that case, FineDedup has to read three pages, i.e., *page 1*, *page 2*, and *page 3*, from flash memory to form the requested data. The read performance penalty can also occur even when there are no duplicate chunks in the requested page. For example, in Fig. 29, *Req 2* has no duplicate chunks in flash memory, thus all the chunks belonging to *Req 2* being written to

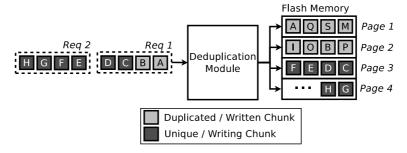

Figure 29: Data fragmentation caused by FineDedup.

flash memory. Because a single page write requires four data chunks, 'E' and 'F' of *Req 2* are written to *page 3* together with 'C' and 'D', and 'G' and 'H' will be written to *page 4* with other data chunks, as shown in Fig. 29. Thus, when the data written by *Req 2* are read later, both *page 3* and *page 4* must be read from flash memory.

One of the feasible approaches that mitigate the read performance overhead is to employ a chunk read buffer. In our observation, the access frequencies of unique chunks are greatly skewed; that is, a small number of popular chunks account for a large fraction of the total accesses to unique chunks in flash memory. For example, according to our analysis under real-world workloads, top 10% of the unique chunks serve more than 70% of the total data read by a host system. By keeping frequently accessed chunks in a chunk read buffer, therefore, FineDedup can reduce a large number of page read operations sent to flash memory.

On the other hands, we have observed that about 39% of read requests to unique pages actually requires two page read operations. In order to further reduce this read performance penalty, FineDedup uses a chunk packing scheme. The key idea of this scheme is to group chunks belonging to the

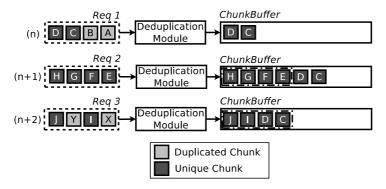

Figure 30: A packing scheme in the chunk buffer.

same logical page in a chunk buffer and then write them to the same physical page together. Fig. 30 shows an example of our chunk packing scheme when three page write requests, *Req 1*, *Req 2*, and *Req 3*, are consecutively issued from a host system. *Req 1* contains two duplicate chunks 'A' and 'B' and two unique chunks 'C' and 'D'. As expected, only 'C' and 'D' out of four chunks are sent to the chunk buffer. The next request *Req 2* does not have any duplicate chunks, so all of them are moved to the chunk buffer. As depicted in Fig. 30, the chunks 'E', 'F', 'G', and 'H' belong to the same logical page and form single page data. Thus, FineDedup writes them to flash memory together, leaving the chunks 'C' and 'D' in the chunk buffer. When *Req 3* is issued with two more unique chunks 'T' and 'J', 'C' and 'D' along with 'T' and 'J' are written to flash memory. All those chunks can be written to the same physical page together because every chunk of each request is not broken up into two pages.

Note that the main objective of this scheme is to prevent chunks of a unique request to be scattered across multiple pages avoiding unnecessary data fragmentation. In order to directly insert a incoming unique request to

chunk buffer, page-sized free space is managed to be always available in the buffer. When there is no free space for the next request and no suitable chunks of requests to form a single page, the chunks of a partially duplicate request is broken up into two pages. Most partially duplicated requests, however, are 3/4-Duplicate pages as shown in Fig. 26, which means there are many requests of one unique chunk in the chunk buffer. Therefore, we can expect that most requests will be written to the same page even when the size of the chunk buffer is not large since it is not quite difficult to find an appropriate chunk to fit a flash page. In the above example, if we assume the chunk buffer can contain 8 chunks and *Req 3* has three unique chunks, only two chunks of *Req 3* will be written along with existing chunks, 'C' and 'D', leaving the other chunk in chunk buffer. A large chunk buffer provides more chance to avoid the request scattering.

Remaining data in the chunk buffer could be lost when a power failure occurs. Recent enterprise SSDs, such as SM825 model manufactured by Samsung, have a large SDRAM cache (e.g., 256 - 512 MB) and use it as a device buffer. Moreover, they support internal cache power protection through the use of capacitors to flush out information in DRAM to flash memory at the event of power failure [53]. In order to keep the reliability in FineDedup, the remaining data in the chunk buffer can be stored to flash memory during power protection procedure as well as the mapping information of the written page. In conclusion for chunk buffer design, there is a trade-off between potential read performance and reliability depending on the chunk buffer size. The size of the chunk buffer, hence, should be determined according to the characteristics of workloads.

#### 5.3.3 Memory Overhead Management

FineDedup handles requested data in the unit of a chunk. Therefore, FineDedup must maintain a chunk-level mapping table that maps a logical chunk address to a physical chunk address in flash memory. Since the size of a chunk is smaller than that of a page, a chunk-level mapping table is much larger than the page-level mapping table. For example, suppose that the page size is 4 KB and the chunk size is 1 KB. In that case, the size of a chunk-level mapping table is four times larger than that of a page-level mapping table.

In order to reduce the amount of memory space required for a mapping table, FineDedup employs a hybrid mapping table which is composed of two types of mapping tables: a page-level mapping table and a chunk-level mapping table. As depicted in Fig. 26, duplicate pages and unique pages still account for a considerable proportion of the total written pages. For these pages, the page-level mapping table is more appropriate because they can be directly mapped to corresponding pages in flash memory. The chunk-level mapping table is required only for partially duplicate pages.

Fig. 31 shows the overall architecture of the hybrid mapping table used in FineDedup. The primary mapping table (PMT) is maintained in the page level while the secondary mapping table (SMT) is maintained in the chunk level. The entry of the PMT is either a physical page address (PPA in Fig. 31) in flash memory or an index of the SMT (chunk address (CA) in Fig. 31).

If the chunk-level mapping is not necessary for a requested page, for example, unique page or duplicate page, the corresponding entry of the PMT

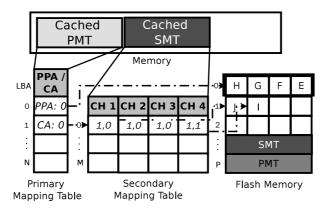

Figure 31: An overview of the demand-based hybrid mapping table.

directly points to the physical address of the newly written page or existing unique page in flash memory, respectively. On the other hand, if a partially duplicate page is requested for writing, FineDedup allocates a new entry in the SMT. As depicted in Fig. 31, each entry of SMT is composed of four fields, each of which points to the physical chunk address in flash memory. FineDedup then updates the new entry so that each field points to the physical chunk address. The corresponding entry of the PMT indicates the newly allocated entry of the SMT.

Using the hybrid mapping table, FineDedup can reduce the amount of memory space for keeping a mapping table. However, the problem of this hybrid mapping approach is that the size of a mapping table can greatly vary according to the characteristics of workloads. For example, if some workloads have many partially duplicate pages, the size of the SMT gets too big. On the other hand, if workloads mostly have unique pages or duplicate pages, the it can be very small. Thus, the hybrid mapping table cannot be directly adopted in real SSD devices whose DRAM size is usually

fixed. To overcome such a limitation, FineDedup adopts a demand-based mapping strategy in which the entire chunk-level mapping table is stored in flash memory while caching only a fixed number of popular entries in DRAM memory. The *Cached PMT* and *Cached SMT* in Fig. 31 represents the cached versions of the PMT and SMT, respectively.

It has been known that the demand-based mapping requires extra page read and write operations [60]. For instance, if a mapping entry for a chunk to be read is not found in the in-memory mapping table, that entry must be read from flash memory while evicting a victim entry to flash memory. The temporal locality present in workload, however, helps keep the number of extra operations small. The mapping information of requests issued in similar times will be stored in the same flash page. Once a mapping page is loaded in memory, hence, most requests issued in similar times are serviced from the mappings in memory.

#### **5.3.4** Experimental Results

In order to evaluate the effectiveness of FineDedup, we performed our experiments using a trace-driven simulator with the I/O traces collected under various applications. The trace-driven simulator modeled the basic operations of NAND flash memory, such as page read, page write and block erase operations, and included several flash firmware algorithms, such as garbage collection and wear-leveling. The proposed FineDedup technique and the existing deduplication techniques were also implemented in our simulator.

For trace collection, we modified the Linux kernel 2.6.32 and collected I/O traces at the level of a block device driver. All the I/O traces include

Trace	Description	Amount of Writes	Amount of Reads
RocksDB	Benchmarking on the Key-value store	3.1 GB	810 MB
GCC+cp	Developing Kernel modules	2.6 GB	66 MB
PC usage	Web surfing, emailing and editing document, etc.	2.5 GB	70 MB
Package Tool	Installing & upgrading software packages	4.9 GB	119 MB

Table 2: A summary of traces used for experimental evaluations.

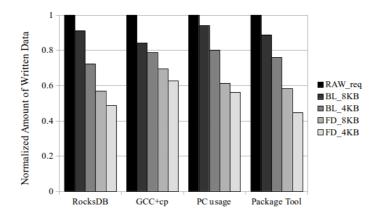

Figure 32: The amount of written data under various schemes.

detailed information about the I/O commands sent to a storage device (e.g., the type of requests, logical block addresses (LBA), the size of requests, etc.) as well as the contents of the data sent to or read from a storage device. We recorded I/O traces while running various real-world applications. The detailed descriptions of these I/O traces are summarized in Table 2.

#### **Effectiveness of FineDedup**

Fig. 32 shows the amount of data written to flash memory by FineDedup over the existing scheme. The results shown in Fig. 32 are normalized to  $RAW\_req$ , which represents the total amount of data written to flash memory without data deduplication. We assume the page-based deduplication technique as a baseline case. The baseline is denoted by  $BL\_4KB$  for a 4 KB flash page and  $BL\_8KB$  for a 8 KB flash page. Our FineDedup technique is denoted by  $FD\_4KB$  and  $FD\_8KB$  for a 4 KB flash page and a 8 KB flash page, respectively. The chunk size in FineDedup is set to 1 KB for a 4 KB flash page and 2 KB for a 8 KB flash page.

As we can see in Fig. 32, the effectiveness of deduplication techniques is highly workload-dependent. The amount of data eliminated by the deduplication technique notably increases when FineDedup is applied in most of the traces except M-media. When we set the chunk size to one fourth of the flash page size, FineDedup removes on average 16% more duplicate data over *BL\_4KB* for a 4 KB flash page. For a 8 KB flash page, it removes more duplicate data, on average by 23% over the existing technique. For Rocksdb, FineDedup saves 37% flash writes over *BL\_8K*. As expected, the benefit of FineDedup mainly derives from the decreased chunk size because it increases the probability of finding and eliminating duplicate data. Especially, Rocksdb trace shows a large number of write requests with little different data during compaction, so FineDedup can effectively identify unchanged data as duplicate while existing deduplication technique regards as unique data.

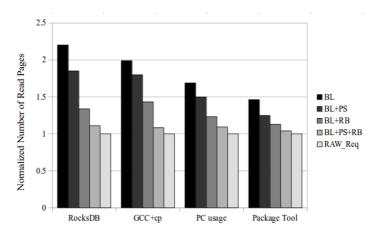

Figure 33: The number of page read operations.

#### **Read Overhead Evaluation**

As explained in Section 5.3.2, fine-grained chunking in FineDedup increases the number of page read operations. Fig. 33 shows the normalized number of page read operations compared with the number of read requests in the workloads.  $RAW\_Req$  indicates the number of original page read requests and BL refers to the number of page read operations of the baseline FineDedup without employing proposed optimization schemes. BL+PS, BL+RB and BL+PS+RB indicate the number of page reads of FineDedup with the proposed packing scheme, the chunk read buffer, and both, respectively. The size of the chunk read buffer was set to 8 MB and the chunk buffer size was set to 200 KB.

As shown in Fig. 33, employing the chunk read buffer is more effective than the packing scheme for reducing additional page read operations in most workloads. This is because the packing scheme is only effective for the requests containing no duplicate chunks whereas the chunk read buffer

can absorb most of the read requests to frequently accessed chunks. FineDedup with both the packing scheme and chunk read buffer incurs on average less than 5% of additional read operations over the existing deduplication technique.

#### **Memory Overhead Evaluation**

As explained in Section 5.3.3, chunk level mapping table requires large memory space to handle partially duplicate pages. In FineDedup, we have proposed the demand-based hybrid mapping table to reduce the required memory size for a mapping table without performance degradations. In Fig. 34, the effectiveness of the proposed mapping table is evaluated in terms of the hit ratio and the amount of additional written data with various memory sizes for the cache. Since the PMT of the hybrid mapping table in FineDeup is the same approach as the DFTL [60], which is a well-known demand-based scheme to exploit the page-level mapping, the overhead of PMT can be estimated from the overhead of DFTL. Thus, in order to focus on the overhead of the SMT, we assume that DFTL is employed as the baseline mapping scheme in our evaluation.

Fig. 34(a) shows the hit ratio of the cached SMT. With a 120 KB cache, more than 95% of the mapping table accesses are absorbed. In addition, Fig. 34(b) shows extra written data caused by the evicted page entries from the SMT cache. Since mapping table accesses occur in the middle of read/write operations, it is important to reduce the amount of written data from evicted page entries in terms of read/write performance. Similar to the hit ratio, the overhead by the eviction becomes almost negligible when the

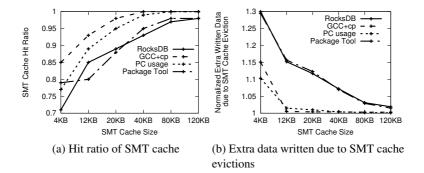

Figure 34: The effectiveness of the demand-based hybrid mapping table in FineDedup with various cache sizes.

cache size is set to 120 KB under most workloads. As a result, FineDedup does not incur a significant memory overhead even when the fine-grained chunking method is not effective.

### Chapter 6

#### **Conclusions**

#### **6.1 Summary and Conclusions**

The cost-per-bit of NAND flash-based solid-state drives (i.e., SSDs) has been steadily improved by uninterrupted semiconductor process scaling and multi-leveling, so that they are how widely used in not only mobile embedded systems but also personal computing systems. However, the limited lifetime of NAND flash memory, as a side effect of recent advanced device technologies, is emerging as one of the main concerns for recent high-performance SSDs, particularly for data center applications.

In this dissertation, we have presented a new stream management technique, PCStream, for multi-streamed SSDs. Unlike existing techniques, PCStream fully automates the process of mapping data to a stream based on PCs. Based on observations that most PCs are effective to distinguish lifetime characteristics of written data, PCStream allocates each PC to a different stream. When a PC has a large variance in their lifetimes, PCStream refines its stream allocation during GC and moves the long-lived data of the current stream to the corresponding internal stream. Our experimental results show that PCStream can improve the IOPS by up to 56% over the existing automatic technique while reducing WAF by up to 69%.

Next, we propose a selective deduplication technique based on the

program context, called PCDedup. By selectively adapt the deduplication, PCDedup can improve the space efficiency of the dedup table as well as the deduplication ratio. PCDedup achieves 23% higher deduplication ratio on average over the baseline technique. Moreover, by reflecting the characteristics of the workload where additional duplication opportunities are limited, 2-level LRU technique also increases up to 38% deduplication ratio over the baseline. Finally, by using a fine-grained deduplication unit, the proposed FineDedup technique increases the amount of data eliminated by data deduplication by up to 37% over the existing page-based deduplication technique.

Since the proposed performance and lifetime improvement techniques only require a small resource overhead and a low time overhead, they can be easily implemented in the existing NAND flash-based storage systems with minimal changes in flash software modules.

#### **6.2** Future Work

## **6.2.1** Supporting applications that have unusal program contexts

The current version of PCStream can be extended. PCStream does not support applications that rely on a write buffer (*e.g.*, MySQL). Similarly, we can make PCStream to support thread pools. In a thread pool, I/O is performed by worker threads. so it obviously won't work unless we somehow capture PC when an I/O is queued to the thread pool.

To address this, we plan to extend PCStream interfaces so that devel-

opers can easily incorporate PCStream into their write buffering modules with minimal efforts. The key insight on this extension is that we should collect PC signatures *at the front-end interface* of an intermediate layer that accepts write requests from other parts of the program.

## 6.2.2 Optimizing read request based on the I/O context

Although PCStream focues on only writes, program contexts are originally used to predict accesses to the cache at the operating system layer. For example, PCs have been used to accurately predict the instruction behavior in the processor's pipeline which allows the hardware to apply power reduction techniques at the right time to minimize the impact on performance [9]. In Last Touch Predictor [10], PCs are used to predict which data will not be used by the processor again and free up the cache for storing or prefetching more relevant data. In PC-based prefetch predictors [11], a set of memory addresses or patterns are linked to a particular PC and the next set of data is prefetched when that PC is encountered again.

Based on the good performance on cache management, we can optimize read request using the program context. For example, when there are some read pattern for a PC (sequential read or repetitive read), we can copy the target page to other chip or channel to maximize read bandwidth for the future read. Moreover, when there is a program context that read specific address many times, we can handle read disturbance problem in advance.

## **6.2.3** Exploiting context information to improve fingerprint lookups

One of the most time-consuming operations in a deduplication system is hash lookup, because it often requires extra I/O operations. Worse, hashes are randomly distributed by their very nature. Hence, looking up a hash often requires random I/O, which is the slowest operation in most storage systems. Also, as previous studies have shown [61], it is impractical to keep all the hashes in memory because the hash index is far too large.

When a deduplication system knows what data is about to be written, it can prefetch the corresponding hashes from the index, accelerating future data writes by reducing lookup delays. For example, a copying process first reads source data and then writes it back. If a deduplication system can identify that behavior at read time, it can prefetch the corresponding hash entries from the index to speed up the write path. Another interesting use case for this context is segment cleaning in log-structured file systems (e.g., Nilfs2) that migrate data between segments during garbage collection.

The I/O context is used to inform the deduplication system of I/O operations that are likely to generate further duplicates (e.g., during a file copy) so that their hashes can be prefetched and cached to minimize random accesses. This hint can be set on the read path for applications that expect to access the same data again.

### 초록

컴퓨팅 시스템의 성능 향상을 위해, 기존의 느린 하드디스크(HDD)를 빠른 낸드 플래시 메모리 기반 저장장치(SSD)로 대체하고자 하는 연구가 최근 활발히 진행되고 있다. 그러나 지속적인 반도체 공정 스케일링 및 멀티 레벨링 기술로 SSD 가격을 동급 HDD 수준으로 낮아졌지만, 최근의 첨단 디바이스 기술의 부작용으로 NAND 플래시 메모리의 수명이 짧아지는 것은 고성능 컴퓨팅 시스템에서의 SSD의 광범위한 채택을 막는 주요 장벽 중 하나이다.

본 논문에서는 최근의 고밀도 낸드 플래시 메모리의 수명 및 성능 문제를 해결하기 위한 시스템 레벨의 개선 기술을 제안한다. 제안 된 기법은 응용 프로그램의 쓰기 문맥을 활용하여 기존에는 얻을 수 없었던 데이터 수명 패턴 및 중복데이터 패턴을 분석하였다. 이에 기반하여, 단일 계층의 단순한 정보만을 활용했던 기존 기법의 한계를 극복함으로써 효과적으로 NAND 플래시 메모리의 성능및 수명을 향상시키는 최적화 방법론을 제시한다.

먼저, 응용 프로그램의 I/O 작업에는 문맥에 따라 고유한 데이터 수명과 중복 데이터의 패턴이 존재한다는 점을 분석을 통해 확인하였다. 문맥 정보를 효과적으로 활용하기 위해 프로그램 컨텍스트 (쓰기 문맥) 추출 방법을 구현 하였다. 프로그램 컨텍스트 정보를 통해 가비지 컬렉션 부하와 제한된 수명의 NAND 플래시 메모리 개선을 위한 기존 기술의 한계를 효과적으로 극복할 수 있다.

둘째, 멀티 스트림 SSD에서 WAF를 줄이기 위해 데이터 수명 예측의 정확성을 높이는 기법을 제안하였다. 이를 위해 애플리케이션의 I/O 컨텍스트를 활용하는 시스템 수준의 접근 방식을 제안하였다. 제안된 기법의 핵심 동기는 데이터 수명이 LBA보다 높은 추상화 수준에서 평가 되어야 한다는 것이다. 따라서 프로그램 컨텍스트를 기반으로 데이터의 수명을 보다 정확히 예측함으로써, 기존기법에서 LBA를 기반으로 데이터 수명을 관리하는 한계를 극복한다. 결론적으로 따라서 가비지 컬렉션의 효율을 높이기 위해 수명이 짧은 데이터를 수명이 긴데이터와 효과적으로 분리 할 수 있다.

마지막으로, 쓰기 프로그램 컨텍스트의 중복 데이터 패턴 분석을 기반으로

불필요한 중복 제거 작업을 피할 수있는 선택적 중복 제거를 제안한다. 중복 데이터를 생성하지 않는 프로그램 컨텍스트가 존재함을 분석적으로 보이고 이들을 제외함으로써, 중복제거 동작의 효율성을 높일 수 있다. 또한 중복 데이터가 발생하는 패턴에 기반하여 기록된 데이터를 관리하는 자료구조 유지 정책을 새롭게 제안하였다. 추가적으로, 서브 페이지 청크를 도입하여 중복 데이터를 제거 할 가능성을 높이는 세분화 된 중복 제거를 제안한다.

제안 된 기술의 효과를 평가하기 위해 다양한 실제 시스템에서 수집 된 I/O 트레이스에 기반한 시뮬레이션 평가 뿐만 아니라 에뮬레이터 구현을 통해 실제 응용을 동작하면서 일련의 평가를 수행했다. 더 나아가 멀티 스트림 디바이스의 내부 펌웨어를 수정하여 실제와 가장 비슷하게 설정된 환경에서 실험을 수행하였다. 실험 결과를 통해 제안된 시스템 수준 최적화 기법이 성능 및 수명 개선 측면에서 기존 최적화 기법보다 더 효과적이었음을 확인하였다. 향후 제안된 기법들이 보다 더 발전된다면, 낸드 플래시 메모리가 초고속 컴퓨팅 시스템의 주 저장장치로 널리 사용되는 데에 긍정적인 기여를 할 수 있을 것으로 기대된다.

**키워드:** 플래시 기반 저장 장치, 저장장치 수명, 임베디드 소프트웨어, 운영체제 **학번:** 2012-30201
